Single-shot measurement of the orbital-angular-momentum spectrum of light

Girish Kulkarni¹, Rishabh Sahu¹, Omar S. Magaña-Loaiza², Robert W. Boyd²,³ & Anand K. Jha¹

The existing methods for measuring the orbital-angular-momentum (OAM) spectrum suffer from issues such as poor efficiency, strict interferometric stability requirements, and too much loss. Furthermore, most techniques inevitably discard part of the field and measure only a post-selected portion of the true spectrum. Here, we propose and demonstrate an interferometric technique for measuring the true OAM spectrum of optical fields in a single-shot manner. Our technique directly encodes the OAM-spectrum information in the azimuthal intensity profile of the output interferogram. In the absence of noise, the spectrum can be fully decoded using a single acquisition of the output interferogram, and, in the presence of noise, acquisition of two suitable interferograms is sufficient for the purpose. As an important application of our technique, we demonstrate measurements of the angular Schmidt spectrum of the entangled photons produced by parametric down-conversion and report a broad spectrum with the angular Schmidt number 82.1.

t was shown by Allen et al. that a photon in a light beam can have orbital-angular-momentum (OAM) values in the integer multiples of $h^2$. This result has made OAM a very important degree of freedom for both classical and quantum information protocols\(^2\)\(^-\)\(^11\). This is because an information protocol requires a discrete basis, and the OAM degree of freedom provides a basis that is not only discrete but can also be high-dimensional\(^12\)\(^-\)\(^15\). This is in contrast to the polarization degree of freedom, which provides a discrete but only a two-dimensional basis\(^2\)\(^-\)\(^3\). High-dimensional quantum information protocols have many distinct advantages in terms of security\(^16\)\(^-\)\(^18\), transmission bandwidths\(^19\)\(^-\)\(^20\), gate implementations\(^21\)\(^,\)\(^22\), supersensitive measurements\(^23\), and fundamental tests of quantum mechanics\(^24\)\(^-\)\(^27\). In the classical domain, the high-dimensional OAM-states can increase the system capacities and spectral efficiencies\(^9\)\(^-\)\(^11\).

One of the major challenges faced in the implementation of OAM-based high-dimensional protocols is the efficient detection of OAM spectrum, and it is currently an active research area\(^28\)\(^-\)\(^37\). There are several approaches to measuring the OAM spectrum of a field. One main approach\(^28\)\(^,\)\(^29\) is to display a specific hologram onto a spatial light modulator (SLM) for a given input OAM-mode and then measure the intensity at the first diffraction order using a single-mode fiber. This way, by placing different holograms specific to different input OAM-modes in a sequential manner, one is able to measure the spectrum. However, this method is very inefficient since the required number of measurements scales with the size of the input spectrum. Moreover, due to the non-uniform fiber-coupling efficiencies of different input OAM-modes\(^38\), this method does not measure the true OAM spectrum. The second approach relies on measuring the angular coherence function of the field and then reconstructing the OAM-spectrum through an inverse Fourier transform. One way to measure the angular coherence function is by measuring the interference visibility in a Mach–Zehnder interferometer as a function of the Dove–prism rotation angle\(^31\)\(^,\)\(^32\). Although this method does not have any coupling-efficiency issue, it still requires a series of measurements for obtaining the angular coherence function. This necessarily requires that the interferometer be kept aligned for the entire range of the rotation angles. A way to bypass the interferometric stability requirement is by measuring the angular coherence function\(^33\)\(^,\)\(^34\) using angular double-slits\(^39\). However, this method also requires a series of measurements and since in this method only a very small portion of the incident field is used for detection, it is not suitable for very low-intensity fields such as the fields produced by parametric down-conversion (PDC). The other approaches to measuring the OAM spectrum include techniques based on rotational Doppler frequency shift\(^35\)\(^,\)\(^36\) and concatenated Mach–Zehnder interferometers\(^37\). However, due to several experimental challenges, these approaches\(^35\)\(^-\)\(^37\) have so far been demonstrated only for fields consisting of just a few modes. Thus the existing methods for measuring the OAM spectrum information suffer from either poor efficiency\(^28\)\(^,\)\(^35\) or strict interferometric stability requirements\(^31\)\(^,\)\(^32\)\(^,\)\(^37\) or too much loss\(^33\)\(^,\)\(^34\). In addition, many techniques\(^28\)\(^,\)\(^33\)\(^,\)\(^34\) inevitably discard part of the field and yield only a post-selected portion of the true spectrum.

In this article, we demonstrate an interferometric technique for measuring the true OAM spectrum in a single-shot manner, that is, by acquiring only one image of the output interferogram using a multi-pixel camera. Since our method is interferometric, the efficiency is very high, and since it involves only single-shot measurements, the interferometric stability requirements are much less stringent.

Results

Theory of single-shot spectrum measurement. The Laguerre-Gaussian (LG) modes, represented as $LG_l^p(\rho, \phi)$, are exact solutions of the paraxial Helmholtz equation. The OAM-mode index $l$ measures the OAM of each photon in the units of $h$, while the index $p$ characterizes the radial variation in the intensity\(^1\). The partially coherent fields that we consider in this article are the ones that can be represented as incoherent mixtures of LG modes having different OAM-mode indices\(^33\). The electric field $E_{\text{in}}(\rho, \phi)$ corresponding to such a field can be written as

$$E_{\text{in}}(\rho, \phi) = \sum_{l,p} A_{lp} LG_l^p(\rho, \phi) = \sum_{l} A_{lp} LG_l^p(\rho)e^{i\phi},$$

where $A_{lp}$ are stochastic variables. The corresponding correlation function $W(\rho_1, \phi_1; \rho_2, \phi_2)$ is

$$W(\rho_1, \phi_1; \rho_2, \phi_2) = \langle E_{\text{in}}^* (\rho_1, \phi_1) E_{\text{in}}(\rho_2, \phi_2) \rangle_c = \sum_{l,p} A_{lp}^* LG_l^p(\rho_1, \phi_1) LG_l^p(\rho_2, \phi_2).$$

Here $\langle \cdot \rangle_c$ represents the ensemble average and $\langle A_{lp}^* A_{lp} \rangle_c = \delta_{lpp} \delta_{l21}$, where $\delta_{l21}$ is the Kronecker-delta function. When integrated over the radial coordinate, the above correlation function yields the angular coherence function: $W(\phi_1, \phi_2) = \int_0^{\infty} \rho d\rho W(\rho, \phi_1; \rho, \phi_2)$, which, for the above field, can be shown to be\(^33\)

$$W(\phi_1, \phi_2) \rightarrow W(\Delta \phi) = \frac{1}{2\pi} \sum_{l=1}^{\infty} S_l e^{-i\Delta \phi},$$

where $S_l = \sum_p \delta_{lpp} \Delta \phi = \phi_1 - \phi_2$, and where we have used the identity $\int_0^{\infty} \rho LG_l^p(\rho) LG_l^p(\rho) d\rho = \delta_{lpp}/2\pi$. The quantity $S_l$ is referred to as the OAM spectrum of the field. It is normalized such that $\sum_l S_l = 1$ and $\int_{-\pi}^{\pi} W(\phi_1, \phi_2)d\phi_1 = 1$. The Fourier transform relation of Eq. (3) is the angular analog of the temporal Wiener–Khinchine theorem for temporally stationary fields (see Section 2.4 of ref. \(^40\)). Therefore, a measurement of $W(\Delta \phi)$ can yield the OAM spectrum of the input field through the inverse Fourier relation

$$S_l = \int_{-\pi}^{\pi} W(\Delta \phi) e^{i\Delta \phi} d\Delta \phi.$$  

Now, let us consider the situation shown in Fig. 1a. A partially coherent field of the type represented by Eqs. (1) and (2) enters the Mach–Zehnder interferometer having an odd and an even number of mirrors in the two arms (shown in Fig. 1c). As illustrated in Fig. 1d, each reflection transforms the polar coordinate as $\rho \rightarrow \rho$ and the azimuthal coordinate as $\phi + \phi_0 \rightarrow \phi + \phi_0$ across the reflection axis (RA). Here $\phi$ is the angle measured from RA, and $\phi_0$ is the angular-separation between RA and the zero-phase axis of the incident mode (dashed axis). The phase $\phi_0$ does not survive in intensity expressions. So, without the loss of any generality, we take $\phi_0 = 0$ for all incident modes. Therefore, for the input incident field $E_{\text{in}}(\rho, \phi)$ of Eq. (1), the field $E_{\text{out}}(\rho, \phi)$ at the output port becomes

$$E_{\text{out}}(\rho, \phi) = \sqrt{K_1} E_{\text{in}}(\rho, -\phi) e^{i(\omega_0 t_1 + \beta_1)} + \sqrt{K_2} E_{\text{in}}(\rho, \phi) e^{i(\omega_0 t_2 + \beta_2)}.$$  

Here, $t_1$ and $t_2$ denote the travel-times in the two arms of the interferometer; $\omega_0$ is the central frequency of the field; $\beta_1$ and $\beta_2$ are the phases other than the dynamical phase acquired in the two arms; $\gamma$ is a stochastic phase which incorporates the temporal...
coherence between the two arms; $k_1$ and $k_2$ are the scaling constants in the two arms, which depend on the splitting ratios of the beam splitters, etc. The azimuthal intensity $I_{\text{out}}(\phi)$ at the output port is defined as $I_{\text{out}}(\phi) \equiv \rho(E_{\text{out}}(\rho, \phi)^*E_{\text{out}}(\rho, \phi))$, and using Eqs. (1)–(4), we can evaluate it to be

$$I_{\text{out}}(\phi) = \frac{1}{2\pi}(k_1 + k_2) + \gamma \sqrt{k_1 k_2} W(2\phi) e^{i\delta} + \text{c.c.} \quad (6)$$

Here, we have defined $\delta \equiv \omega_0(t_2 - t_1) + (t_2 - t_1)$, and $\gamma = \langle e^{i\phi_l} \rangle$ quantifies the degree of temporal coherence. The intensity expression in Eq. (6) is very different from the output intensity expression one obtains in a conventional Mach–Zehnder interferometer with a Dove prism having either odd/odd or even/even number of mirrors in the two interferometric arms. In Eq. (6), the output intensity and the angular correlation function both depend on the detection-plane azimuthal angle $\phi_l$. As a result, the angular correlation function $W(2\phi)$ comes out encoded in the azimuthal intensity profile $I_{\text{out}}(\phi)$. In contrast, in the conventional Mach–Zehnder interferometers, the output intensity has no azimuthal variation; one measures the angular correlation function by measuring the interference visibility of the total output intensity as a function of the Dove prism rotation angles. For a symmetric spectrum ($S_\text{i} = S_{\text{in}} = (S_i + S_{\text{in}})/2$), we have, using the formula in Eq. (4)

$$S_\text{i} = \int_{-\pi}^{\pi} W(2\phi) e^{i2\phi_l} d(2\phi) = \frac{1}{2\pi \cos \delta_i k_1 k_2} \int_{-\pi}^{\pi} I_{\text{out}}(\phi) - \frac{k_1 k_2}{2\pi} \cos(2\phi_l) d\phi_l.$$

So, if the precise values of $k_1$, $k_2$, $\gamma$, and $\delta$ are known then a single-shot measurement of the output interferogram $I_{\text{out}}(\phi)$ yields the angular coherence function $W(2\phi)$ and thereby the OAM spectrum $S_\text{i}$. Here, by “a single-shot measurement” we mean recording one image of the output interferogram using a multi-pixel camera. The recording may involve collecting several photons per pixel for a fixed exposure time of the camera.

Theory of two-shot noise-insensitive spectrum measurement. Although it is in principle possible to measure the OAM spectrum in a single-shot manner as discussed above, it is practically extremely difficult to do so because of the requirement of a very precise knowledge of $k_1$, $k_2$, $\gamma$, and $\delta$. Moreover, obtaining a spectrum in this manner is susceptible to noise in the measured $I_{\text{out}}(\phi)$, which results in errors in the measured spectrum. We now show that it is possible to eliminate this noise completely while also relinquishing the need for a precise knowledge of $k_1$, $k_2$, $\gamma$, and $\delta$, just by acquiring one additional output interferogram. We present our analysis for a symmetric spectrum, that is, for ($S_\text{i} = S_{\text{in}} = (S_i + S_{\text{in}})/2$) (see Methods section for the non-symmetric case). Let us assume that the experimentally measured output azimuthal intensity $T_{\text{out}}(\phi)$ at $\delta$ contains some noise $T_{\text{in}}(\phi)$ in addition to the signal $I_{\text{out}}(\phi)$, that is,

$$T_{\text{out}}(\phi) = I_{\text{in}}(\phi) + \frac{1}{2\pi}(k_1 + k_2) + 2\gamma \sqrt{k_1 k_2} W(2\phi) \cos \delta.$$

Now, suppose that we have two interferograms, $T_{\text{out}}^\text{in}(\phi)$ and $T_{\text{out}}^\text{in}(\phi)$, measured at $\delta = \delta_i$ and $\delta = \delta_i$ respectively. The difference in the intensities $\Delta T_{\text{out}}(\phi) = T_{\text{out}}^\text{in}(\phi) - T_{\text{out}}^\text{in}(\phi)$ of the two interferograms is then given by

$$\Delta T_{\text{out}}(\phi) = \Delta I_{\text{in}}(\phi) + 2\gamma \sqrt{k_1 k_2} \cos \delta_i \cos \delta_i W(2\phi),$$

where $\Delta I_{\text{in}}(\phi) = I_{\text{in}}^\text{in}(\phi) - I_{\text{in}}^\text{in}(\phi)$ is the difference in the noise intensities. Multiplying each side of the above equation by $e^{i2\phi_l}$, using the formula in Eq. (4), and defining the measured OAM spectrum as $\frac{S_\text{i}^\text{in}}{\int_{-\pi}^{\pi} \Delta T_{\text{out}}(\phi) e^{i2\phi_l} d(2\phi)} = \int_{-\pi}^{\pi} \Delta I_{\text{out}}(\phi) e^{i2\phi_l} d\phi_l,$
azimuthal intensities, and the measured spectrum for the synthesized input

We get

$$\Delta I_o(\phi) \approx 0$$

Now, in situation in which

We see that in situations in which there is no shot-to-shot variation in noise, that is, \( \Delta I_o(\phi) = 0 \), the measured OAM-spectrum \( \tilde{S}_l \) is same as the true input OAM-spectrum \( S_l \) up to a scaling constant. One can thus obtain the normalized OAM-spectrum in a two-shot manner without having to know the exact values of \( k_1, k_2, \gamma, \delta_1, \) or \( \delta_2 \). Nevertheless, in order to get a better experimental signal-to-noise ratio, it would be desirable to have \( \gamma \approx 1, k_1 \approx k_2 \approx 0.5, \delta_1 \approx 0, \) and \( \delta_2 \approx \pi \). Now, in situation in which \( \Delta I_o(\phi) \neq 0 \), it is clear from Eq. (8) that the measured spectrum will have extra contributions. However, since we do not expect very rapid azimuthal variations in \( \Delta I_o(\phi) \), the extra contributions should be more prominent for modes around \( l = 0 \) and should die down for large-\( l \) modes.

**Measuring lab-synthesized OAM spectra.** We now report the experimental demonstrations of our technique for laboratory-synthesized, symmetric OAM spectra. As shown in Fig. 1a, a He–Ne laser is spatially filtered and made incident onto a Holoeye Pluto SLM. The \( L_{G_l=-}(\rho, \phi) \) modes are generated using.

![Experimental results obtained with the lab-synthesized fields. a, b Measured output interferograms and the corresponding azimuthal intensities for input \( L_{G_l=0}(\rho, \phi) \) modes with \( l = 1, 4, \) and 16 for \( \delta_1 \approx 2m \pi \) and \( \delta_2 \approx (2m+1)\pi \), respectively, where \( m \) is an integer. c Measured output interferograms, the azimuthal intensities, and the measured spectrum for the synthesized input field with a Gaussian OAM-spectrum. d Measured output interferograms, the azimuthal intensities, and the measured spectrum for the synthesized input field with a Rectangular OAM-spectrum. In all the above azimuthal intensity plots, the red lines are the experimental plots and the black lines are the theoretical fits.](image-url)
the method by Arrizon et al.41 and then made incident into the Mach–Zehnder interferometer shown in Fig. 1c. The measured interferogram and the corresponding azimuthal intensity \( I_{az}(\phi) \) for a few LG\(_l\) modes for \( \delta_1 \approx 2\pi n_1 \) and \( \delta_2 \approx (2m + 1)\pi \), where \( m \) is an integer, are presented in Fig. 2a, b, respectively. A very good match between the theory and experiment indicates that the LG\(_l\) modes produced in our experiments are of very high quality. By contolling the strengths of the synthesized LG\(_l\) modes for \( l \) ranging from \( l = -20 \) to \( l = 20 \), we synthesize two separate fields: one with a rectangular spectrum and the other one with a Gaussian spectrum. The representative interferogram corresponding to a particular field as input is obtained by adding individual interferograms for \( l \) ranging from \( l = -20 \) to \( l = 20 \). Two such representative interferograms, one with \( \delta = \delta_1 \) and the other one with \( \delta = \delta_2 \) are recorded for each field.

Figure 2c, d show the measured output interferograms, the corresponding azimuthal intensity \( I_{az}(\phi) \) computed using Eq. (8) for the synthesized Gaussian and Rectangular OAM spectra, respectively. We find a very good match between the synthesized spectra and the measured spectra. There is some mismatch in the measured spectra for low-\( l \) modes. We attribute this to SLM imperfections, various wave-front aberrations, and the non-zero shot-to-shot noise variation \( \Delta I_{az}(\phi) \).

**Measuring angular Schmidt spectrum of entangled states.** The state of the two-photon field produced by PDC has the following Schmidt-decomposed form when the detection system is sensitive only to the OAM-mode index33:

\[
|\psi_2\rangle = \sum_{l=-\infty}^{\infty} \sqrt{S_l} |l\rangle_s |-l\rangle_i. \tag{9}
\]

Here \( s \) and \( i \) stand for signal and idler photons, respectively, \(|l\rangle\) represents a mode with OAM-mode index \( l \), and \( S_l \) is referred to as the angular Schmidt spectrum. The angular Schmidt spectrum quantifies the dimensionality and the entanglement of the state in the OAM basis32, 42, 43. There are a variety of techniques for measuring the angular Schmidt spectrum32, 38, 39, 44, 45. In the context of spatial entanglement, there has even been a theoretical proposal46 and its subsequent experimental implementation47 for measuring the spatial Schmidt spectrum in a single-shot manner using coincidence detection. However, all the above mentioned work, including the single-shot work in the spatial domain46, 47, are sensitive to noise and require either a very precise knowledge of the experimental parameters, such as beam splitting ratio, or a very stable interferometer. In contrast, as an important experimental application of our technique, we now report an experimental measurement of the angular Schmidt spectrum of the PDC photons that not only is a single-shot, noise-insensitive technique but also does not require coincidence detection.

As derived in ref. 33, the angular coherence function \( W_s(\phi_1, \phi_2) \) corresponding to the individual signal or idler photon has the following form:

\[
W_s(\phi_1, \phi_2) = \frac{1}{2\pi} \sum_{l=-\infty}^{\infty} S_l e^{-i\Delta \phi}, \tag{10}
\]

where \( S_l = \sum_p a_{lp} \) is the OAM spectrum of individual photons. Comparing Eqs. (9) and (10), we find that the OAM spectrum of individual photons is same as the angular Schmidt spectrum of the entangled state. Therefore, it is clear that one can measure the angular Schmidt spectrum in a single-shot manner by measuring the OAM-spectrum of individual photons in a single-shot manner. As depicted in Fig. 1b, entangled photons are produced by PDC with collinear type-I phase matching. The photons are collected by a lens arrangement whose collection angle is larger than the emission cone-angle of the crystal. This ensures that no part of the produced field is discarded from the measurement and thus that the true spectrum is measured. This field is then made incident into the Mach–Zehnder interferometer of Fig. 1b. For a type-I collinear down-conversion with a 2-mm thick beta barium borate (BBO) crystal and a 0.85-mm beam-waist pump laser, the
measured output interferograms and the corresponding azimuthal intensities for two values of $\Delta$ have been shown in Fig. 3a, b. Figure 3c shows the normalized measured spectrum as computed using Eq. (8) and the normalized theoretical spectrum as calculated using the formalism of ref. 42. The near-perfect match without the use of any fitting parameter shows that we have indeed measured the true theoretical angular Schmidt spectrum of PDC photons. There is some mismatch for low-$\ell$ values, which we attribute to the very small but finite shot-to-shot noise variation $\Delta I_\ell(\phi)$. The angular Schmidt number computed as $K = 1/\left(\sum \Delta I_\ell^2\right)$ is $K = 82.1$, which, to the best of our knowledge, is the highest-ever reported angular Schmidt number so far.

**Discussion**

In conclusion, we have proposed and demonstrated a single-shot technique for measuring the angular coherence function and thereby the OAM spectrum of light fields that can be represented as mixtures of modes with different OAM values per photon. Our technique involves a Mach–Zehnder interferometer with the central feature of having an odd and an even number of mirrors in the two interferometric arms, and it is very robust to noise and does not require precise characterization of setup parameters, such as beam splitting ratios, degree of temporal coherence, etc. This technique also does not involve any inherent post-selection of the field to be measured and thus measures the true OAM spectrum of a field. As an important application of this technique, we have reported the measurement of a very high-dimensional OAM-entangled states in a single shot manner, without requiring coincidence detection. For such high-dimensional states, our technique improves the time required for measuring the OAM coincidence detection. For such high-dimensional states, our analysis for a non-symmetric spectrum, that is, when $S_l \neq S_d$, condition is not necessarily met. Just as in the case of symmetric spectrum, let us assume that the measured azimuthal intensity $T_{\ell m}(\phi)$ at the output contains the noise term $I_{\ell m}(\phi)$ in addition to the signal $I_{\ell m}(\phi)$. Thus,

$$T_{\ell m}(\phi) = I_{\ell m}(\phi) + I_{\ell m}(\phi)$$

Now, suppose we have two interferograms measured at two different values of $\phi$, say at $\phi_1$ and $\phi_2$. The difference $\Delta T_{\ell m}(\phi)$ in the intensities of the two interferograms is then given by

$$\Delta T_{\ell m}(\phi) = T_{\ell m}(\phi) - T_{\ell m}(\phi)$$

$$= \Delta I_{\ell m}(\phi) + \gamma\sqrt{k_{\ell}} [W(2\ell)e^{i\phi} + W^*(2\ell)e^{i\phi}]$$

$$- W(2\ell)e^{i\phi} - W^*(2\ell)e^{i\phi}],$$

where $\Delta I_{\ell m}(\phi) = I_{\ell m}(\phi) - I_{\ell m}(\phi)$ is the difference in the noise intensities. Unlike in the case of symmetric spectrum, $\Delta T_{\ell m}(\phi)$ is not proportional to the angular coherence function $W(2\ell)$. Multiplying each side of Eq. (12) by $e^{i\phi}$ and using the angular Wiener–Khintchine relation $S_l = \int_{-\ell}^{\ell} W_l(2\ell)e^{i\phi}d(2\ell)$, we obtain

$$\int_{-\ell}^{\ell} \Delta T_{\ell m}(\phi)e^{i\phi}d(2\ell) = \int_{-\ell}^{\ell} \Delta I_{\ell m}(\phi)e^{i\phi}d(2\ell)$$

$$+ \gamma\sqrt{k_{\ell}}[S_{\ell}e^{i\phi} + S_{\ell}e^{-i\phi} - S_{\ell}e^{i\phi} - S_{\ell}e^{-i\phi}].$$

Now, multiplying each side of Eq. (12) by $e^{-i\phi}$ and using the angular Wiener–Khintchine relation $S_l = \int_{-\ell}^{\ell} W_l(2\ell)e^{-i\phi}d(2\ell)$, we obtain

$$\int_{-\ell}^{\ell} \Delta T_{\ell m}(\phi)e^{-i\phi}d(2\ell) = \int_{-\ell}^{\ell} \Delta I_{\ell m}(\phi)e^{-i\phi}d(2\ell)$$

$$+ \gamma\sqrt{k_{\ell}}[S_{\ell}e^{-i\phi} + S_{\ell}e^{i\phi} - S_{\ell}e^{-i\phi} - S_{\ell}e^{i\phi}].$$

Adding Eqs. (13) and (14), we get

$$\int_{-\ell}^{\ell} \Delta T_{\ell m}(\phi)(\cos(2\ell)d(2\ell) = \int_{-\ell}^{\ell} \Delta I_{\ell m}(\phi)(\cos(2\ell)d(2\ell)$$

$$+ \gamma\sqrt{k_{\ell}}[\{S_{\ell} - S_{\ell}\} \cos(\delta) - \cos(\delta)].$$

Subtracting Eq. (14) from Eq. (13), we get

$$\int_{-\ell}^{\ell} \Delta T_{\ell m}(\phi)(\sin(2\ell)d(2\ell) = \int_{-\ell}^{\ell} \Delta I_{\ell m}(\phi)(\sin(2\ell)d(2\ell)$$

$$- \gamma\sqrt{k_{\ell}}[\{S_{\ell} - S_{\ell}\} \sin(\delta) - \sin(\delta)].$$

**Theory of non-symmetric OAM-spectrum measurement**

This section presents our analysis for a non-symmetric spectrum, that is, when $S_l \neq S_d$, condition is not necessarily met. Just as in the case of symmetric spectrum, let us assume that the measured azimuthal intensity $T_{\ell m}(\phi)$ at the output contains the noise term $I_{\ell m}(\phi)$ in addition to the signal $I_{\ell m}(\phi)$. Thus,
Now the question is how should one define the spectrum so that the defined spectrum becomes proportional to the true spectrum. Upon inspection we find that for the non-symmetrical case it is not possible to define the spectrum the way we did it in the case of symmetric spectrum. Nevertheless, in the special situation in which $\delta_x + \delta_y = \pi/2$, it is possible to define the measured spectrum just like we did it in the symmetric case. Let us consider the situation when $\delta_x = \theta$ and $\delta_y = \pi/2 - \theta$ such that $\delta_x + \delta_y = \pi/2$. Equations (13) and (16) for this situation can be written as

$$f_x \Delta I_{x+} (\phi) | \cos (2 \Delta \phi) | d(2 \phi) = f_x \Delta I_{x+} (\phi) \cos (2 \Delta \phi) | d(2 \phi) + \frac{\pi}{\sqrt{\kappa \kappa}} \delta (\phi + \sin \phi \theta) S_i,$$

(17)

and

$$f_x \Delta I_{x+} (\phi) | \sin (2 \Delta \phi) | d(2 \phi) = f_x \Delta I_{x+} (\phi) \sin (2 \Delta \phi) | d(2 \phi) + \frac{\pi}{\sqrt{\kappa \kappa}} \delta (\phi - \sin \phi \theta) S_i.$$  

(18)

Adding Eqs. (17) and (18), we get

$$f_x \Delta I_{x+} (\phi) | \cos (2 \Delta \phi) | d(2 \phi) + \frac{\pi}{\sqrt{\kappa \kappa}} \delta (\phi + \sin \phi \theta) S_i = f_x \Delta I_{x+} (\phi) | \cos (2 \Delta \phi) | d(2 \phi) + \frac{\pi}{\sqrt{\kappa \kappa}} \delta (\phi - \sin \phi \theta) S_i.$$  

(19)

So, now if we define the measured spectrum $S_i$ to be

$$S_i = f_x \Delta I_{x+} (\phi) | \cos (2 \Delta \phi) | d(2 \phi) + \frac{\pi}{\sqrt{\kappa \kappa}} \delta (\phi + \sin \phi \theta) S_i,$$

we get

$$S_i = f_x \Delta I_{x+} (\phi) | \cos (2 \Delta \phi) | d(2 \phi) + \frac{\pi}{\sqrt{\kappa \kappa}} \delta (\phi - \sin \phi \theta) S_i.$$  

(20)

In situations in which the noise neither has any explicit functional dependence on $\theta$ nor has any shot-to-shot variation, we have $\Delta I_\theta (\phi) = 0$. Thus the defined spectrum $S_i$ becomes proportional to the true spectrum $S$. We see that just as in the case of symmetric spectrum, one does not have to know the exact values of $\kappa_1$, $\kappa_2$, $\gamma$, and $\theta$. The only thing different in this case is that one has to take the two shots such that $\delta_x + \delta_y = \pi/2$.
