Abstract. This study evaluated the impact of macronutrient omission on nutritional disorders and the in vitro growth of Bletia catenulata. The experiment was performed in a growth room, with a controlled environment, in the biotechnology laboratory of the Campus of Chapadão do Sul (CPCS/UFMS). The experiment consisted of a completely randomized design, with seven treatments and four replications, corresponding to the following treatments: complete treatment (N, P, K, Ca, Mg, S, B, Mn, Zn, Cu, Fe, and Mo), nitrogen omission (–N), phosphorus omission (–P), potassium omission (–K), calcium omission (–Ca), magnesium omission (–Mg), and sulfur omission (–S) in B. catenulata. After detecting the symptoms, plant height, leaf area, dry weight, micronutrient content in the shoot, micronutrient accumulation in the shoot, and visual symptoms of nutritional deficiency were evaluated. The –N, –P, –Ca, and –Mg treatments hindered plant growth and dry weight yield. The deficiency of each nutrient resulted in morphological changes, which were verified by typical visual symptoms of nutritional disorder for each nutrient.

The genus Bletia Ruiz & Pav. is composed of more than 35 species. Only two have been registered in Brazil, and one of them is Bletia catenulata. This species has a terrestrial habit and sympodial growth, presenting commercial potential as a result of the rare beauty of its leaves and flowers. Reports of this species occurring in different locations in the Brazilian territory, such as Tocantins and Maranhão (Silva et al., 1995), Minas Gerais (Araújo et al., 2002), Distrito Federal (Batista et al., 2005), São Paulo (Ferreira et al., 2010), and Mato Grosso do Sul (Barros et al., 2018), as well as in other countries such as Bolivia (Vásquez et al., 2003) and Paraguay (Schinini, 2010) have been documented.

B. catenulata was found in four different sites in the northeastern region of the Mato Grosso do Sul State, always with low frequency. In some sites, it is exposed to environments that undergo human disturbance. In addition, this orchid has terrestrial habits and superficial roots, and often occurs near watercourses (Paiva Neto et al., 2015). However, in the literature we only found one study involving aspects related to the cultivation of this species, carried out by Paiva Neto et al. (2015). These authors demonstrated that the in vitro germination of seeds of all fruit resulting from different pollinations was hindered and the water used was deionized. To each experimental unit was composed of a glass bottle (height, 13.5 cm; diameter, 8 cm) containing 70 mL nutrient solution (Hoagland and Arnon, 1950) adjusted to pH 5.8 before the autoclaving process at 120 °C, 1 atm, and 20 min. The prepared solution was semisolid with nutrients and agar. For the Fe supply, we used the complexed form with Fe-EDDHA (YaraVita Rexolin®), and the water used was deionized. To each bottle, B. catenulata seedlings were added and the bottle sealed with transparent film paper. The process for obtaining the seedlings followed the methodology recommended by Paiva Neto et al. (2015).

The seedlings were selected according to uniformity and were transplanted into the culture medium (using a pair of tweezers in a Filter Flux® horizontal laminar flow hood) with the respective treatments, and were cultivated until deficiency symptoms appeared. The plants transferred to the nutrient-deficient solution came from a culture medium with all nutrients available. All plants were analyzed daily for visual symptoms of nutritional disorders related to

Results and Discussion

Nitrogen. B. catenulata plants subject to the complete treatment and –N treatment presented N content in the shoot dry weight of 13.10 and 8.60 g kg⁻¹, respectively, indicating that N omission decreases the element leaf content (Table 1). N accumulation in the plant shoot in nutrient solution with –N decreased 72% when compared with the complete treatment (Table 2). N omission was the one that decreased plant growth, according to height and leaf area, which reflected on shoot dry weight accumulation in relation to the complete treatment (Table 3). Rodrigues et al. (2011) also verified the importance of N content and sources in orchid nutrition, obtaining a significant reduction in the growth of Cattleya loddigesii ‘Type’ species at low concentrations of this element.

Table 3. Plant height, leaf area, and shoot dry weight of Bletia catenulata plants as a function of the treatments.

| Treatments | Plant (cm) | Leaf area (cm²) | Dry wt (g) |
|------------|------------|----------------|------------|
| Complete   | 19.18 a    | 21.01 a        | 0.08 a     |
| –N         | 3.08 d     | 2.40 c          | 0.04 b     |
| –P         | 11.33 bc   | 9.86 bc         | 0.05 b     |

strategy to meet N demands, the plant de- toriates stomal proteins to release N compounds, such as amino acids (Feller et al., 2008). This symptom has also been reported by Ji-Yong et al. (2012) in cucumber.

Phosphorus. The P content in the shoot dry weight was greater in the complete treatment than in the –P treatment (Table 1). Thus, the P content in the shoot dry weight of the –P treatment (0.55 g kg⁻¹) is less than that of the complete treatment (1.85 g kg⁻¹), indicating the nutrient deficiency in the plant. The –P treatment reduced P accumulation in the shoot by 81.25% (Table 2). Growth parameters were affected by the –P treatment, which resulted in shorter plant height, fewer number of leaves, and less leaf area, culminating in lower shoot dry weight yield (Table 3). Similar results were reported by Prado and Vidal (2008). Mengel and
Kirby (1987) stated that the development of P-deficient plants reduces because several processes are affected, such as the synthesis of proteins and nucleic acids.

P omission led to visual symptoms of deficiency. Plants were a dull dark green, especially the older leaves (Supplemental Fig. 1B). This result was due to the high mobility of this nutrient in the phloem, causing the P-deficient plant to redistribute the nutrient to the developing tissues (Hawkesford et al., 2012).

In addition, older leaves were narrower. The authors studied nutrient omission in millet and noticed that older leaves of plants subject to P omission were dark green and narrower. According to Taiz et al. (2017), P deficiency induces the excessive production of anthocyanins. This phenomenon may lead to the appearance of purple spots, which did not occur in Bletia catenulata plants.

Potassium. B. catenulata plants subject to the –K treatment and complete treatment presented K content in the shoot dry weight of 5.25 and 19.95 g kg⁻¹, respectively (Table 1). Thus, K accumulation decreased by 85.55% in relation to the complete treatment (Table 2). K omission significantly affected plant height when compared with the complete treatment (Table 3).

These results can be attributed to the problems caused by K deficiency in metabolic processes because this nutrient is an essential enzymatic activator, acting in photosynthesis and cell osmoregulation, and synthesis of nucleic acids, carbohydrates, and proteins (Hawkesford et al., 2012).

K omission resulted in visual symptoms of deficiency, causing chlorosis and necrosis on the lower third leaves (Supplemental Fig. 1C). These symptoms occurred as a result of the high mobility of this nutrient in the phloem. Therefore, in the absence of this element, K accumulation in older leaves is translocated to younger leaves. Pathak et al. (2014) observed that K-deficient plants usually accumulate soluble N compounds, such as amines, aminobutyric acid, and putrescines. The authors also suggest that putrescines might be responsible for the necrotic spots from the chlorosis symptoms on the leaves of K-deficient plants.

Leaves also presented symptoms of shrinkage, with edges facing upward. The cause of this symptom was excessive water loss by the plant, making it flaccid. According to Prado (2008), K-deficient plants have low water use efficiency, causing poor control of the opening and closing of the stomata, and consequently increasing transpiration and water loss rates.

Similar symptoms have been described by Mattos et al. (2002) and Prado and Leal (2006) in a –K treatment carried out with Brachiaria and sunflower plants, respectively.

Calcium. The complete treatment resulted in 10.25 g kg⁻¹ Ca content in the shoot. Conversely, the –Ca treatment presented a Ca content in the shoots of 2.00 g kg⁻¹ (Table 1). Therefore, Ca accumulation decreased by almost 90% in relation to the complete treatment (Table 2).

The –Ca treatment affected plant height and leaf area, which decreased by 44.7% and 43.36%, respectively (Table 3), when compared with the complete treatment. Consequently, shoot dry weight production decreased.

Ca omission resulted in the development of symptoms of nutritional disorder in new leaves because the redistribution of this nutrient via the phloem is limited and is characterized by irregular, rough, undulated, and reduced growth (Supplemental Fig. 1D). These symptoms can be attributed to the involvement of Ca in cell structuring, stabilization, expansion, and stretching (Hochmuth et al., 2004).

Magnesium. The Mg content in the shoot was 2.05 and 0.45 g kg⁻¹ in the complete treatment and –Mg treatment, respectively (Table 1). Therefore, Mg content decreased significantly in the –Mg treatment when compared with the complete treatment. These results led to less Mg accumulation in the –Mg treatment (Table 2). All macro-nutrient contents in the shoot decreased when the –Mg treatment was applied (Table 1).

The –Mg treatment reduced plant growth significantly, resulting in shorter plants and smaller leaf area, leading to lower shoot dry weight accumulation in relation to the complete treatment (Table 3). Moreover, it resulted in symptoms of nutritional disorder in B. catenulata, which manifested in the lower third leaves as a result of the high Mg mobility to younger tissues of active growth.

Symptoms were characterized by a slight yellowing between veins as Mg is a component of the chlorophyll molecule (Verbruggen and Hermans, 2013). The chlorophyll content might have decreased, causing chlorosis in these leaves, leading to a thick reticulate aspect, with leaf blade wrinkling. These symptoms were similar to those observed by Prado and Leal (2006) and Silva (2013), who investigated Mg omission in sunflower and pepper, respectively.

Sulfur. The S content in the shoot of the complete treatment was 2.95 g kg⁻¹. The –S treatment presented an S content in the shoot of 0.75 g kg⁻¹ (Table 1). Thus, S accumulation decreased by 84.6% when the –S treatment was applied (Table 2).

S omission significantly reduced plant height. However, it did not affect shoot dry weight yield and shoot leaf area when compared with the complete treatment (Table 3). The treatment resulted in the development of nutritional disorder symptoms in B. catenulata plants, with new leaves that were light green (Supplemental Fig. 1E), demonstrating the main physiological S sink (Silva et al., 2003). This result is consistent with those reported by Malavolta (1997), who confirmed the yellowing of younger leaves as a typical symptom.

Conclusion

The –N, –P, –Ca, and –Mg treatments hindered plant growth and dry weight yield. The deficiency of each nutrient resulted in morphological changes, which were verified by typical visual symptoms of nutritional disorders for each nutrient.
