A theoretical model of Leidenfrost’s temperature

Sergey Gavrilyuk and Henri Gouin

1Aix Marseille University, CNRS, IUSTI, UMR 7343, Marseille, France

The Leidenfrost effect is a phenomenon in which a liquid, poured onto a surface significantly hotter than the liquid’s boiling point, produces a layer of vapor that prevents the liquid from rapid evaporation. Rather than making physical contact, a drop of water levitates above the surface.

The temperature above which the phenomenon occurs is called Leidenfrost’s temperature. The reason for the existence of Leidenfrost’s temperature, which is much higher than the boiling point of the liquid, is not fully understood and predicted. Here we prove that Leidenfrost’s temperature corresponds to a bifurcation in the solutions of equations describing evaporation of a non-equilibrium liquid–vapor interface. For water, the theoretical values of obtained Leidenfrost’s temperature, and that of the liquid bulk which is smaller than the boiling point of liquid, fit the experimental results found in the literature.

Keywords: Leidenfrost effect, non-equilibrium thermodynamics, capillarity effect, dynamic interfaces.

I. INTRODUCTION

When water is projected onto a moderately heated metal plate, it spreads out, starts to boil and evaporates very quickly. Things are quite different when the metal is incandescent: the water temperature remains below the boiling temperature, divides into numerous droplets that roll, bounce and at the end of their life they either take–off or explode. These phenomena are well described in [1–8]. An analytical model of these figures and movements has been proposed in [9, 10]. Observations also show that the droplets perform translational and rotational motions. These movements lead to geometrically beautiful patterns. Photographic and stroboscopic tools were then used to describe the experiments, but the effect can be seen with the naked eye. Such a phenomenon is qualitatively very well described in [11]. An analytical model of these figures and movements has been proposed in [11].

This Leidenfrost effect, called also film boiling, was carefully observed in 1756 by the German physician J. G. Leidenfrost. Leidenfrost had well understood the cause of the film boiling phenomenon: there is no contact between the burning solid and water, the liquid evaporates in the vicinity of the solid and levitates on a cushion of steam [12].

In 1844, M. Boutigny had also experimented on himself some curious facts related to the phenomenon like plunging his hand in a bath of molten iron without burning himself [13]. Fiery coal can reach about 540 degrees Celsius; candidates for walking on hot coals must moisten their feet to benefit from the Leidenfrost effect. At the end of the 19th century, physicists multiplied astonishing experiments like transforming water into ice by pouring it into a crucible containing sulphuric acid and heated to red hot [14].

Today, it is no longer these curiosities that are the subject of in-depth studies, but importance of this phenomenon in all industrial sectors where high temperatures are handled [15–17]. The boiling crisis is often the first step in an explosive process that is generated by the contact of a hot surface and a liquid. If it is well dominated by metallurgists for the hardening of metals, it is not yet the case in other fields where it is the cause of important accidents. For example, in the oil industry, at the bottom of the distillation towers is oil at a temperature of about 400 degrees Celsius. In these towers, very dry steam is injected at the same temperature. When, due to a malfunction in the installation, liquid water is injected, the explosion that occurs is so violent that it destroys most of the distillation plates [18]. In nuclear industry, several accidents were initiated by the phenomenon. In 1961, for the American SL–1 reactor at Idaho State Laboratory, an unexpected lifting of a control bar caused water to be projected over the core onto the vessel which, despite its weight of 13 tons, sheared the pipes to which it was connected and rose about 3 meters. In 1986, the film boiling phenomenon occurred in Chernobyl, and in 2011 in Fukushima, creating major nuclear accidents. The largest terrestrial explosion ever recorded, that of Krakatoa volcano (in 1883) corresponding to 200 megatons of TNT, is also due to the contact of lava at high temperature with sea water.

Since the layer is thin, we can neglect the gravitational forces. A schematic description of such a thought experiment
FIG. 1. Sketch of a quasi-one-dimensional transverse fluid flow. Domain (a) is a thin liquid layer of temperature \( T_a \); (i) is the liquid-vapor discontinuity interface which is a very thin region of few nanometers thickness of vapor having the same temperature \( T_i \); and (ii) is the non-isothermal and non-homogeneous part of the vapor flow; the temperature increases from \( T_i \) to \( T_w \). Region (c) is the part of the vapor region where the flow is not one-dimensional: the vapor escapes along the solid surface. The arrows represent the flow direction.

is shown in Figure 1. The liquid water layer \( a \) is assumed to be separated from the water vapor layer by a liquid–vapor interface \( i \). We assume that the liquid water layer is under atmospheric pressure \( p_0 \), and that the interface and thin liquid bulk are at the same temperature \( T_i \). The vapor layer between the liquid–vapor interface \( i \) and the heated surface \( W \) is decomposed into two parts: an intermediate part \( b \) where the temperature varies from \( T_i \) to \( T_w \), and the part \( c \) at temperature \( T_w \) where the vapor is evacuated along the solid surface \( W \). It has been observed that the boiling crisis is always accompanied by a specific frequency regime. We assume that the vapor density oscillations immediately appear near the interface and disappear at the end of the part \( b \). We only need to model the phase transition at the interface \( i \) and non-isothermal and non-homogeneous one-dimensional vapor flow in the part \( b \). For the part \( b \), we use a phase-field model \([24, 28]\). It allows us to find the bifurcation temperature below which the existence of such a configuration is not possible. Without claiming that our model will solve all the problems posed by the film boiling phenomenon, we believe that it can help to understand the phenomenon by explaining the origin of the Leidenfrost temperature.

To simplify the presentation of the article, we have separate the paper into six sections and three appendices. In Section 2, we present the classical van der Waals equation of state. Section 3 studies the thermo-mechanical van der Waals–Korteweg model across the liquid-vapor interface and in the vapor part of the flow. Sections 4 and 5 study the dimensionless governing equations of one-dimensional flows. In Section 6 the numerical calculations of the governing equations are performed related to experimental data to obtain the Leidenfrost temperature value. A conclusion ends this presentation. Some technical details are shown in Appendices A, B and C.

II. THE VAN DER WAALS EQUATION OF STATE

We adapt to our problem the simplest model for the description of equilibrium liquid–vapor interfaces for water: the van der Waals equation of state. Experimental values of physical quantities for water at the boiling temperature \( T_0 = 373.15^\circ \text{Celsius} \) are presented in International System of Units (SI) (see \([29]\)):

\[
p_0 \approx 101325 \text{ Pa}, \quad v_g \approx 1.673 \text{ m}^3/\text{kg}, \quad v_l \approx 0.001043 \text{ m}^3/\text{kg},
\]

where \( p_0 \) is the atmospheric pressure, \( v_g \) and \( v_l \) are specific volumes of vapor and liquid water at phase equilibrium, respectively. Here and in what follows, we use the IS system. The van der Waals equation of state is:

\[
p = \frac{RT}{v-b} - \frac{a}{v(v-b)},
\]

where \( a, b, R \) are constant, \( v = 1/\rho \) is the specific volume, and \( \rho \) is the density. When \( v \) is large, the van der Waals equation yields the equation of state of perfect gas \( p v = RT \). At a given temperature \( T \), one obtains the chemical potential \( \mu \) (defined up to an additive constant), where \( dm = \nu dp \):

\[
\mu(\nu, T) = -RT \log(v-b) + \frac{RT b}{v-b} - \frac{2a}{v},
\]

To adapt the equation \([1]\) to our problem, we calculate the values of \( a, b \) and \( R \) to satisfy the chemical and mechanical equilibrium at atmospheric pressure \( p_0 \). The equilibrium Maxwell conditions of liquid–vapor interface are:

\[
\begin{align*}
\frac{RT_0}{v_g} - \frac{a}{v_g^2} &= \frac{RT_0}{v_l} - \frac{a}{v_l^2} = p_0, \\
\mu(v_g, T_0) &= \mu(v_l, T_0).
\end{align*}
\]

At \( T_0 = 373.15^\circ \text{Celsius} \), we obtain:

\[
a \approx 1.52 \times 10^3 \text{ m}^3 \text{ s}^{-2}, \quad b \approx 9.2 \times 10^{-4} \text{ m}^3 \text{ kg}^{-1},
\]

\[
R \approx 456 \text{ m}^2 \text{ s}^{-2} \text{ K}^{-1}.
\]

The obtained values of \( a \) and \( b \) are thus different from those calculated for the thermodynamic critical point \([30]\). However, the value of \( R \) is close to that of the perfect gas constant which is \( 462 \text{ m}^2 \text{ s}^{-2} \text{ K}^{-1} \). This is the reason why we will use in the following the same notation \( R \) for this constant. We define a characteristic specific volume \( v_0 \) of the vapor phase as:

\[
p_0 v_0 = RT_0,
\]

which gives

\[
v_0 \approx 1.68 \text{ m}^3 \text{ kg}^{-1}.
\]

Van der Waals’ model is a qualitatively realistic equilibrium model even far from the boiling point. Indeed, when we consider vapor and liquid water near \( 160^\circ \text{Celsius} \), we obtain from system \([5]\) other values of coefficients \( a, b \) and \( R \):

\[
a \approx 1.40 \times 10^3 \text{ m}^3 \text{ s}^{-2}, \quad b \approx 9.3 \times 10^{-4} \text{ m}^3 \text{ kg}^{-1},
\]

\[
R \approx 447 \text{ m}^2 \text{ s}^{-2} \text{ K}^{-1}.
\]
III. A CONTINUOUS THEORY OF CAPILLARITY

We now introduce the second gradient theory of fluids where the internal energy depends on density gradients \[31\], \[32\]. In fact, such a model is a special case of the Cahn and Hilliard phase field model \[27\]. It has been developed, in particular, by Rowlinson and Widom \[28\].

The second gradient theory, conceptually more straightforward than the Laplace theory, can be used to construct a continuous theory for fluid interfaces. Rowlinson and Widom wrote: the view that the interfacial region may be treated as matter in bulk, with a local free-energy density that is that of hypothetically uniform fluid of composition equal to the local composition, with an additional term arising from the non-uniformity, and that the latter may be approximated by a gradient expansion typically truncated in second order, is then most likely to be successful and perhaps even quantitatively accurate. The essential difference compared to specific compressible fluids is that the specific internal energy depends not only on the density \(\rho = 1/\nu\), specific entropy \(\eta\), but also of \(\nabla \rho\). The specific internal energy \(\alpha\) characterizes both the compressibility and capillarity properties of the fluid. Due to fluid isotropy, this energy depends only on the norm of density gradient. The simplest expression of the specific energy is:

\[
\alpha = \varepsilon(\rho, \eta) + \frac{\lambda}{2\rho} |\nabla \rho|^2, \quad \lambda = \text{const} > 0. \tag{4}
\]

Here \(\varepsilon(\rho, \eta)\) is the classical specific energy and \(\lambda\) is a capillary coefficient which is related to the surface tension coefficient \[28\] (Chapter 3, pp. 50-57). Such a gradient density dependent energy appears not only in the vicinity of the thermodynamic critical point, but also in the case of large fluctuations.

A. Conservative motion

For conservative motion, the van der Waals–Korteweg equations of non-homogeneous capillary fluids can be derived from the Hamilton principle of stationary action by using the well-known Lagrangian \[33\], \[35\] :

\[
\mathcal{L} = \rho \left( \frac{|u|^2}{2} - \alpha - \Omega \right),
\]

where \(u\) is the velocity, \(\Omega\) is the specific potential of external forces, and \(\alpha\) is given by \(\Omega\). The usual constraints are the mass and entropy conservation laws:

\[
\frac{\partial \rho}{\partial t} + \text{div}(\rho \mathbf{u}) = 0, \tag{5}
\]

and

\[
\frac{\partial \rho \eta}{\partial t} + \text{div}(\rho \eta \mathbf{u}) = 0. \tag{6}
\]

We refer to calculations in \[31\], \[32\], \[37\] to directly write the momentum equations in the form:

\[
\frac{\partial \rho \mathbf{u}}{\partial t} + \text{div}(\rho \mathbf{u} \otimes \mathbf{u} - \sigma) + \rho \nabla \Omega = 0, \tag{7}
\]

where

\[
\sigma = -\left( p - \frac{\lambda}{2} |\nabla \rho|^2 - \lambda \rho \Delta \rho \right) I - \lambda \nabla \rho \otimes \nabla \rho,
\]

\[
p = \rho^2 \frac{\partial \varepsilon(\rho, \eta)}{\partial \rho}.
\]

Due to a small thickness of a fluid layer, gravitational forces will be neglected. As a consequence of \[3\], \[5\] and \[7\], one obtains the energy equation :

\[
\frac{\partial e}{\partial t} + \text{div}\left( e \mathbf{u} - \sigma \mathbf{u} - \lambda \frac{\partial p}{\partial t} \nabla \rho \right) = 0, \quad e = \rho \left( \frac{|u|^2}{2} + \alpha \right). \tag{8}
\]

In the one-dimensional case, the \(x\)-axis is drawn perpendicular to the liquid layer and heated surface (see Figure \[1\]). The governing equation \(\tag{7}\) is written as:

\[
\frac{\partial}{\partial t}(\rho \mathbf{u}) + \frac{\partial}{\partial x} (\rho |\mathbf{u}|^2 + P) = 0, \tag{9}
\]

where

\[
P = p + k, \quad \text{with} \quad k = \frac{\lambda}{2} \left( \frac{\partial \rho}{\partial x} \right)^2 - \lambda \rho \frac{\partial^2 \rho}{\partial x^2}. \tag{10}
\]

Here \(t\) denotes the time, \(x\) the space variable perpendicular to the liquid layer and heated surface, \(u\) is the corresponding scalar velocity. Note that \(P\) can be considered as a total pressure: it is the sum of the thermodynamic pressure \(p\) and capillary pressure \(k\). If \(k\) is positive (negative), then \(P > p\) (\(P < p\)). At a given temperature \(T\), Eq. \(\tag{9}\) admits the conservation law:

\[
\frac{\partial u}{\partial t} + \frac{\partial}{\partial x} \left( \frac{|u|^2}{2} + \mu(\rho, T) - \lambda \frac{\partial^2 \rho}{\partial x^2} \right) = 0, \tag{11}
\]

associated with chemical potential \(\mu\) (a particular case \(\mathbf{3}\) of \(\mu\) is calculated for the van der Waals equation of state).

Depending on other additional constraints (isothermal or isobaric processes), we consider the chemical potential or the specific enthalpy instead of the specific internal energy (the details are further explained in Appendices \[8\] and \[9\]).

B. One-dimensional stationary vapor motion

In the rest of the paper, one supposes that the consumed liquid is fed by an external pump that allows the motion to
be steady. We assume one-dimensional flow in the x direction of the domain (b) (see Figure 1). The viscosity is negligible because the evaporation process is very slow. In the one-dimensional stationary case, Eq. (5) yields:

\[ p u = q, \quad q = \text{const}, \]  

where \( q \) represents the constant flow rate of the fluid.

Equation (9) writes:

\[ \frac{d}{dx} \left( \rho u^2 + P \right) = 0, \]  

(13)

- Through the liquid–vapor interface, Eq. (9) implies the jump condition:

\[ [P + q^2 v] = 0, \]  

i.e.

\[ P_i - p_0 + q^2 (v_i - v_l) = 0, \]  

(14)

where the index \( i \) refers to the interface: \( v_i = 1/\rho_i \) (\( v_g = 1/\rho_g \)) the liquid (vapor) specific volume at interface \( i \), \( P_i \) is the total pressure in the vapor phase on the interface, and \( p_0 \) is the pressure in the liquid bulk on the interface, and the square brackets mean the difference of values across interface \( i \). Since the liquid layer is thin, the gravity is not taken into account, thus the interface liquid thermodynamic pressure is the atmospheric pressure \( p_0 \).

- In domains (b), we obtain from (13):

\[ P_i - p_w + q^2 (v_i - v_w) = 0, \]  

where the index \( w \) corresponds to the heated surface \( W \). The vapor on the boundary between \( b \) and \( c \) is assumed to be homogeneous of specific volume \( v_w \) and temperature \( T_w \). Thus, the total pressure is only the thermodynamic pressure part \( p_w \). The difference with Eq. (14) yields:

\[ p_w - p_0 + q^2 (v_w - v_l) = 0. \]  

(15)

- The motion in the bulk (a) and the jump through the interface is assumed to be isothermal. Consequently, we have to use the conservation law (11). The corresponding jump relation is:

\[ \left[ \frac{u^2}{2} + \mu(\rho, T_i) - \lambda \frac{d^2 \rho}{dx^2} \right] = 0, \]  

(16)

where \( \mu(\rho, T_i) \) is defined by (2) with \( T_i \) being the interface temperature that also coincides with the liquid bulk temperature near the interface. Equation (16) can be considered as a dynamical Maxwell rule (see also Appendix B.1).

- The vapor motion in domain (b) is not isothermal. The viscosity of the vapor phase is negligible, so the equation of motion (13) is unchanged. The equation of the energy balance (8) in the vapor phase must take into account the heat exchange in the vapor region. Such a balance equation is in the form:

\[ \left( (e + P) u - \lambda \frac{d \rho}{dx} u \right)_{p_w, T_i} - \left( (e + P) u - \lambda \frac{d \rho}{dx} u \right)_{p_l, T_l} = \dot{Q}_w - \dot{Q}_i. \]  

(17)

Compared to (8), we added in the total energy the balance of heat fluxes \( \dot{Q}_w - \dot{Q}_i \). Also, since the flow volume is fixed, it changes the expression of \( e \) (for proof, see Appendix B.2):

\[ e = \rho (u^2/2 + H) \quad \text{with} \quad H = H + \frac{\lambda}{2 \rho} \left( \frac{d \rho}{dx} \right)^2, \quad H = e + \frac{p_0}{\rho}. \]

Thus, \( H \) is the specific enthalpy of capillary fluid at pressure \( p_0 \), and \( H \) is the enthalpy of a homogeneous fluid at pressure \( p_0 \). The expression of \( \dot{P} \) is given by (10). In the domain (c) near the surface \( W \) the density becomes homogeneous and the balance law (17) becomes:

\[ \left( (e + P) u - \lambda \frac{d \rho}{dx} u \right)_{p_w, T_i} - \left( (e + P) u \right)_{p_l, T_l} = \dot{Q}_w - \dot{Q}_i. \]  

(18)

The vapor density strongly varies near and through the interface.

At the interface, considered as a discontinuity, an extra condition must be added on both sides of the interfacial discontinuity:

\[ \frac{d \rho}{dx} = 0. \]  

(19)

This additional condition (19) is fundamental in the rest of our paper. It is recalled and explained in Appendix A. Also, condition (19) is obtained and analyzed in [35, 38, 39]. Physically, it means the absence of microenergy concentration at the surface of discontinuity. Such a condition also appears when a capillary fluid is in contact with a surface when the surface is neither attractive or repulsive [40–42].

The density jump implies \( d^2 \rho/dx^2 < 0 \), and consequently, due to (10), \( k > 0 \) (this property is analyzed in Fig. 8 upper diagram of Appendix C).

The vapor at temperature \( T_w \) is assumed homogeneous. Using the relation (18) complemented by (19), we get:

\[ \frac{1}{2} q^2 + p_i v_i q - \lambda \frac{d^2 \rho_i}{dx^2} q + H_i q + H_i = \frac{1}{2} q^2 + p_w v_w q + H_w q + \dot{Q}_w. \]

Here indices “l” and “w” mean values of variables at the interface and surface, respectively. In the above relation the second
derivative of the density \( \rho_v \) is \textit{a priori} non-vanishing. Since \( k = -\lambda \rho_v \frac{d^2 \rho_v}{dx^2} \) and \( P_i = p_i + k \), we get:

\[
\frac{1}{2} q^2 v_g^2 + H_i + p_i v_g + \frac{\dot{Q}_i}{q} = \frac{1}{2} q^2 v_w^2 + H_w + p_w v_w + \frac{\dot{Q}_w}{q}\quad (20)
\]

Let us underline that:

\[
p_i = p(v_g, T_i), \quad p_w = p(v_w, T_w).
\]

From Eq. (1), we have (30):

\[
\varepsilon = \int c_v(T) dT - \frac{a}{v},
\]

where \( c_v(T) \) is the specific heat of water vapor at constant volume. Equation (20) implies:

\[
\frac{1}{2} q^2 (v_g^2 - v_w^2) + \int_{v_g}^{v_w} c_v(T) dT + 2 k v_g +

2 \left( \frac{RT v_g}{v_g - b} - \frac{RT v_w}{v_w - b} \right) - \frac{a}{v_g} + \frac{a}{v_w} + \frac{\dot{Q}_i}{q} - \frac{\dot{Q}_w}{q} = 0.
\]

We approximate the vapor equation of state by \( p v_g \approx RT \), \( p_w v_w \approx RT \), and introduce

\[
c_p(T) = c_v(T) + R,
\]

corresponding to the specific heat at constant pressure which depends only on temperature \( T \). We obtain from (21):

\[
\frac{1}{2} q^2 (v_g^2 - v_w^2) + \int_{v_g}^{v_w} c_p(T) dT + 2 k v_g + 

+ R (T_i - T_w) + \frac{\dot{Q}_i}{q} - \frac{\dot{Q}_w}{q} = 0,
\]

(22)

To transform a liquid into saturated vapor, we need to supply latent heat \( L \). At a given temperature, and for the van der Waals equation of state, the energy of a saturated vapor is approximately independent on the pressure. Indeed, considering the internal energy as a function of \( v \) and \( T \), one has:

\[
\varepsilon(v_g, T) - \varepsilon(v_{gs}, T) = a \left( \frac{1}{v_{gs}} - \frac{1}{v_g} \right),
\]

where \( v_{gs} \) is the specific volume of saturated vapor at pressure \( p_s \) (index \( s \) means saturated), and \( v_g \) is the specific volume of vapor at pressure \( p_0 \). Compared to the latent heat value, this variation is small even for large variation of the specific volume of the vapor and we can thus assume that \( \varepsilon(v_g, T) \approx \varepsilon(v_{gs}, T) \). Let \( L(T) \) be the specific heat of the saturated vapor (specific latent heat). One has:

\[
L(T_i) - L(T_w) = (\varepsilon(v_{gs}, T_i) + p_i v_{gs}) - (\varepsilon(v_{gs}, T_w) + p_w v_{gs}).
\]

The saturated vapor equation of state being approximated as a perfect gas :

\[
p_i v_{gs} \approx RT_i, \quad \text{and} \quad p_w v_{gs} \approx RT_w.
\]

Hence,

\[
L(T_i) - L(T_w) \approx \varepsilon(v_{gs}, T_i) - \varepsilon(v_{gs}, T_w) + R(T_i - T_w).
\]

At atmospheric pressure, the water vapor equation of state can also be approximated as a perfect gas:

\[
p_0 v_{gs} \approx RT_i, \quad \text{and} \quad p_0 v_{gs} \approx RT_w.
\]

The specific latent heat is the amount of heat that must be supplied to a pure liquid, in our case water, to produce the phase transition. Thus

\[
\frac{\dot{Q}_i}{q} - \frac{\dot{Q}_w}{q} = L(T_i) - L(T_w).
\]

This is in agreement with (6, 43). Thus, Eq. (22) yields:

\[
\frac{1}{2} q^2 (v_g^2 - v_w^2) + \int_{v_g}^{v_w} c_p(T) dT + 2 k v_g +

+ R (T_i - T_w) + L(T_i) - L(T_w) = 0,
\]

IV. DIMENSIONLESS EQUATIONS OF MOTION

We now consider the dimensionless form of the governing equations. The dimensionless variables are denoted by the same letters but with an additive \textit{tilde sign}. In particular, van der Waals equation of state (11) in dimensionless form is:

\[
\tilde{p} = \frac{p}{p_0}, \quad \tilde{v} = \frac{v}{v_0}, \quad \tilde{T} = \frac{T}{T_0}, \quad \tilde{\dot{p}} = \frac{\dot{p}}{p_0}, \quad \tilde{\dot{\tilde{v}}} = \frac{\dot{\tilde{v}}}{v_0}, \quad \tilde{\tilde{q}} = \frac{\tilde{q}}{q_0}
\]

where \( p_0, T_0 \) are defined in Section (11) and \( v_0 \) is defined from \( p_0 v_0 = RT_0 \). We also introduce the dimensionless variables associated with capillary pressure term, specific volumes and flow rate:

\[
\tilde{p}_i = \frac{p_i}{p_0}, \quad \tilde{k} = \frac{k}{p_0}, \quad \tilde{v}_{gs} = \frac{v_{gs}}{v_0}, \quad \tilde{v}_i = \frac{v_i}{v_0}, \quad \tilde{\tilde{q}} = \frac{\tilde{q}}{q_0}
\]

with \( q_0 = \sqrt{\frac{p_0}{v_0}} \).

The equation (13) takes the following form:

\[
\tilde{p}_i - 1 + \tilde{\tilde{q}}^2 (\tilde{v}_{gs} - \tilde{v}_i) = 0,
\]

The dimensionless flow rate \( \tilde{\tilde{q}} \) is very small. Indeed, when the solid surface temperature is close to the Leidenfrost temperature, the lifetime of liquid dramatically increases, typically by a factor of 500 associated with the existence of a vapor layer isolating the liquid bulk. For example, a millimeter liquid layer on a duralumin surface at 200° Celsius is observed to float for more than a whole minute (6, 44, 45). So, the fluid velocity due to the liquid evaporation is about
The water vapor at pressure \( p_0 \) can be considered as a perfect gas and we obtain from Eqs. (13)–(15):

\[
p_w \approx P_i \approx p_0, \quad p_0 v_w \approx RT_w.
\]

In dimensionless form we get:

\[
\tilde{v}_w \approx \tilde{T}_w \quad \text{and} \quad \tilde{P}_i \approx \tilde{p}_w \approx 1.
\]

The pressure in vapor at temperature \( T_w \) is also the atmospheric pressure \( p_0 \).

From \( p_i v_{\text{g}_i} = RT_i \), we obtain as a consequence of motion equation in domain (i):

\[
\tilde{T}_i = \tilde{p}_i \tilde{v}_{\text{g}_i} = (\tilde{P}_i - \tilde{k}) \tilde{v}_{\text{g}_i} \quad \text{and} \quad \tilde{P}_i \approx 1.
\]

The limit case corresponds to:

\[
T_i = \tilde{v}_{\text{g}_i}.
\]

We hypothesize that the condition (26) defines the value of the Leidenfrost temperature. Indeed, as we have already mentioned, the total pressure \( P \) is composed of the thermodynamic pressure \( p \) and the capillary pressure \( k \). When \( k \) is positive, the thermodynamic pressure near the interface will be smaller than the atmospheric pressure in the vapor portion of the fluid. Therefore, a thermodynamic pressure gradient lifts the droplet. This lifting force can therefore be considered as a kind of Archimede force (buoyancy force). In the following we will show that this hypothesis fits with experimental observations.

### V. DIMENSIONLESS EQUATIONS OF ENERGY

#### A. Liquid–vapor interface (i)

The condition (16) across the liquid–vapor interface writes:

\[
\frac{1}{2} q^2 v_{g_i}^2 + \mu(v_{\text{g}_i}, T_i) + k v_{\text{g}_i} = \frac{1}{2} q^2 \tilde{v}_i^2 + \mu(v_i, T_i),
\]

and Eq. (17) yields:

\[
\frac{1}{2} q^2 v_{g_i}^2 + k v_{\text{g}_i} - R T_i \left\{ \log \left( \frac{v_{\text{g}_i} - \tilde{b}}{v_i - \tilde{b}} \right) - b \left( \frac{1}{v_{\text{g}_i} - b} - \frac{1}{v_i - b} \right) \right\}
\]

\[
+ 2a \left( \frac{1}{v_i} - \frac{1}{v_{\text{g}_i}} \right) = 0.
\]

As proved in Section 4 we can neglect \( q^2 \) and one obtains:

\[
\tilde{k} \tilde{v}_{\text{g}_i} - \tilde{T}_i \left\{ \log \left( \frac{\tilde{v}_{\text{g}_i} - \tilde{b}}{\tilde{v}_i - \tilde{b}} \right) - b \left( \frac{1}{\tilde{v}_{\text{g}_i} - b} - \frac{1}{\tilde{v}_i - b} \right) \right\}
\]

\[
+ 2a \left( \frac{1}{\tilde{v}_i} - \frac{1}{\tilde{v}_{\text{g}_i}} \right) = 0.
\]

#### B. Non-isothermal vapor-layer (b)

For the specific heat at constant pressure \( c_p \), we choose a quadratic model in temperature (see Figure 2).

\[
c_p(T) = H_1 + 2 H_2 T + 3 H_3 T^2.
\]

By integration, we obtain:

\[
\int_{T_w}^{T_i} c_p(T) dT = H_1 (T_i - T_w) + H_2 \left( T_i^2 - T_w^2 \right) + H_3 \left( T_i^3 - T_w^3 \right).
\]

This is the custom to consider locally a linear approximation for \( L(T) \),

\[
L(T) = L_0 + L_1 T \quad \text{where} \quad L_1 < 0.
\]

With (28) and (29), Eq. (23) becomes:

\[
\frac{1}{2} q^2 \left( v_{\text{g}_i}^2 - v_i^2 \right) + 2 k v_{\text{g}_i} + H_1 (T_i - T_w) + H_2 \left( T_i^2 - T_w^2 \right)
\]

\[
+ H_3 \left( T_i^3 - T_w^3 \right) + R (T_i - T_w) + L_1 (T_i - T_w) = 0.
\]

Neglecting terms associated with \( q^2 \), dimensionless form of Eq. (30) writes:

\[
2 \tilde{k} \tilde{v}_{\text{g}_i} + \tilde{H}_1 \left( \tilde{T}_i - \tilde{T}_w \right) + \tilde{H}_2 \left( \tilde{T}_i^2 - \tilde{T}_w^2 \right) + \tilde{H}_3 \left( \tilde{T}_i^3 - \tilde{T}_w^3 \right)
\]

\[
+ \left( \tilde{T}_i - \tilde{T}_w \right) + L_1 \left( \tilde{T}_i - \tilde{T}_w \right) = 0,
\]

where

\[
\tilde{H}_1 = \frac{H_1}{R}, \quad \tilde{H}_2 = \frac{H_2 T_0}{R}, \quad \tilde{H}_3 = \frac{H_3 T_0^2}{R}, \quad \tilde{L}_1 = \frac{L_1}{R}.
\]

#### C. Consequences

In dimensionless form, Eq. (24) writes:

\[
\left( \tilde{v}_i - \tilde{b} \right) \tilde{v}_i^2 - \tilde{T}_i \tilde{v}_i^2 + \left( \tilde{v}_i - \tilde{b} \right) \tilde{a} = 0.
\]

Using (25), one obtains:

\[
\tilde{k} \tilde{v}_{\text{g}_i} = \tilde{v}_{\text{g}_i} - \tilde{T}_i.
\]

Taking account of Eqs. (27), (31) and (32), and by using relation (33), the system allowing to solve our problem is:
is formed. The condition \( \tilde{v}_i - \tilde{T}_i - \tilde{T}_f \left( \log \left( \frac{\tilde{v}_i - \tilde{b}}{\tilde{v}_f - \tilde{b}} \right) - \tilde{b} \left( \frac{1}{\tilde{v}_i - \tilde{b}} - \frac{1}{\tilde{v}_f - \tilde{b}} \right) \right) + 2 \tilde{a} \left( \frac{1}{\tilde{v}_i} - \frac{1}{\tilde{v}_f} \right) = 0, \)

\[
2 \left( \tilde{v}_i - \tilde{T}_i \right) + \tilde{H}_1 \left( \tilde{T}_i - T_w \right) + \tilde{H}_2 \left( \tilde{T}_i^2 - T_w^2 \right) + \tilde{H}_3 \left( \tilde{T}_i^3 - T_w^3 \right) + \left( \tilde{T}_i - \tilde{T}_w \right) + \tilde{L}_1 \left( \tilde{T}_i - \tilde{T}_w \right) = 0, \]

\[
\tilde{T}_i - \left( \tilde{v}_i - \tilde{b} \right) \left( \frac{\tilde{a}}{\tilde{v}_i} - 1 \right) = 0. \tag{34}
\]

System (34) is a system of three equations relatively to unknowns \( \tilde{v}_i, \tilde{v}_f, \tilde{T}_f. \)

VI. NUMERICAL STUDY

A. Values of specific isobaric capacities of water vapor

The table, giving the values of specific isobaric capacities for water vapor, is taken from [28, 46].

| \( T \) \( ^\circ \text{C} \) | 90 | 100 | 120 | 140 | 160 | 180 | 200 |
|---|---|---|---|---|---|---|---|
| \( T \) \( ^\circ \text{K} \) | 363 | 373 | 393 | 413 | 433 | 453 | 473 |
| \( c_p \) \( \text{kJ} \text{kg}^{-1} \text{K}^{-1} \) | 2042.9 | 2080 | 2177 | 2310.9 | 2488.3 | 2712.9 | 2989.5 |

TABLE I. Isobaric heat capacity of water vapor is expressed in \( \text{kJ} \text{kg}^{-1} \text{K}^{-1}. \) The different temperature values are given together in degrees Celsius and Kelvin.

The following quadratic relation is used linking the heat capacity at constant pressure (in \( \text{kJ} \text{kg}^{-1} \text{K}^{-1} \)) as a function of the temperature \( T \) expressed in degrees Kelvin:

\[ c_p(T) = 8329 + 37.13 T - 0.05460 T^2. \tag{35} \]

Then

\[
\int_{T_w}^{T_f} c_p(T)dT = H_1 \left( T_f - T_w \right) + H_2 \left( T_f^2 - T_w^2 \right) + H_3 \left( T_f^3 - T_w^3 \right),
\]

with

\[ H_1 = 8329, \quad H_2 = 18.56, \quad H_3 = -0.01820. \]

Here and in the following, we do not indicate SI–dimensions of \( H_i \) coefficients. The experimental values of \( c_p \) are given in Table II. The corresponding approximation (35) is shown in Fig. 2. We see that Relation (35) fits perfectly with experiment values.

B. Values of latent heat of vaporization for water

The table giving the values of latent heat of vaporization for water as a function of temperature is taken from [28, 46].

\[ L(T) = 3295 - 2800 T \tag{36} \]

\[ L(T) = 3385 - 2900 T \tag{37} \]

TABLE II. The latent heat of liquid water to be transformed into vapor is expressed in \( \text{kJ} \text{kg}^{-1}. \) The different temperature values are given both in degrees Celsius and Kelvin.

These two close approximations are shown in Fig. 3. What matters is the difference of the latent heats \( L(T_f) \) and \( L(T_w). \) Hence, only the slope in \( T \) is relevant. As we will see, the variation of 3% of slopes between (36) and (37), implies a sensible variation of the Leidenfrost temperature.

For the first linear approximation (36) the corresponding Table III is formed. The condition \( \tilde{v}_f = \tilde{T}_f \) corresponds to the fact that \( k \) changes its sign. The value of \( T_w \) associated with bifurcation (26) is our definition of the Leidenfrost temperature which will be denoted by \( T_L. \) From the Table III one can...
The intersection of the two corresponding curves for the first linear approximation \( \tilde{T} \) and for the value of \( T_w = 1.23 \) corresponding to \( T_w = 185^\circ \) Celsius. The intersection point is not sensitive to the choice of parameters \( \tilde{a} \) and \( \tilde{b} \).

In the literature, a wide range of values of Leidenfrost’s temperature were measured depending on the surface characteristics. It is the main reason we give two close approximations for the latent heat of vaporisation. These two approximations are very close but the two temperatures \( T_L \), are noticeably different. Such quite wide dispersion of values of the Leidenfrost temperature was experimentally observed. In our model, the temperature \( T_L \approx 150^\circ \) Celsius corresponds to the lowest value experimentally obtained, but depending on the characteristics of the surface, the Leidenfrost temperature can be much higher than \( T_L \approx 204^\circ \) Celsius.

Another important observation results in the computation of temperature \( T_i \) of the liquid bulk. The temperature of the liquid was first measured in the 19th century by Boutigny who discovered that temperature \( T_i \) is lower than \( T_w \). Precise measurements give the temperature of liquid bulk between 92° and 94° Celsius. In our model, the temperature of interface is \( T_i \approx 93.5^\circ \) Celsius corresponding to \( T_i \approx 0.983 \). For both approximations \( \tilde{T} \) and \( \tilde{v} \) the \( T_i \) values are the same. This result is another confirmation of the consistency of our model.

Based on the variation of \( k \) one can simply explain the Leidenfrost phenomenon as follows. If \( k > 0 \), the thermodynamic pressure \( p \) is lower in the vapor phase just near the liquid-vapor interface compared to the pressure \( p_w \) near the surface. This results in a detachment of the liquid film from the surface. On the contrary, if \( k < 0 \), the thermodynamic pressure \( p \) is higher, and liquid film wets the surface causing a violent boiling. In fact the whole process is highly non-stationary and cannot be described by the stationary equations. However, our approach gives a reasonable estimation of the Leidenfrost temperature.

VII. CONCLUSION

We study the film boiling phenomenon in the framework of the internal capillarity model.

A first important result is the capillary pressure term \( k \) allows us to understand the phenomenon and to determine the Leidenfrost temperature. The boiling crisis corresponds to \( k > 0 \), and Leidenfrost’s temperature to \( k = 0 \). The model predicts...
FIG. 5. Graphs associated with the $k$ values in the second linear approximation [37]. The $x$-axis is associated with the Celsius temperature and the $y$-axis with the pressure $k$ expressed in Pascal. The dots represented $k$ values calculated with the software Mathematica™. In this case, the Leidenfrost temperature is $T_L \approx 204{^\circ}C$.

FIG. 6. Contour–graphs associated with the two first equations of system [44] are shown in the case $\tilde{T}_w = 123$, when $\tilde{T}_i$ is eliminated from the third equation. The $Z$–shape curve corresponds to the equation (34)2, the second curve corresponds to (34)1. The horizontal (vertical) axis indicates dimensionless vapor and liquid specific volumes, respectively. The curves intersect transversally in a unique point. These graphs prove that solution is little sensitive to the approximation of physical parameters.

the Leidenfrost temperature which fits with experimental results. A second important result is the estimation of the temperature of the liquid bulk. It is proved that its value is below the boiling temperature at atmospheric pressure. This result is also compatible with the experimental data on the liquid bulk temperature.

### Appendix A: Extra-condition at dynamical liquid-vapor interfaces

Extra-condition (19) does not come from conservation laws. It is a natural boundary condition coming from Lagrangian formulation of the problem. It already appeared in the study of discontinuous solutions of dispersive equations (35, 38, 39). To give a proof in one-dimensional case, we consider a general action functional:

\[
a(y) = \int L(y, y') dx,
\]

\(y(x)\) is an unknown function, and the integral is taken over a finite interval \(I\). The values of \(y(x)\) are fixed at the ends of interval \(I\). We are looking for \(y(x)\) on which the functional is extremal and we do not assume that \(y(x)\) is smooth. The
variation of $a$ can be written as:

$$\delta a = \int\left( \frac{\delta L}{\delta y} \delta y + \frac{d}{dx} \left( \frac{\partial L}{\partial y'} \delta y' \right) \right) dx,$$

with $\frac{\delta L}{\delta y} = \frac{\partial L}{\partial y} - \frac{d}{dx} \left( \frac{\partial L}{\partial y'} \right)$.

In the case of non-smooth (or "broken") extremal curves, the same Euler–Lagrange equation should be satisfied for each smooth part of the extremal curve:

$$\frac{\delta L}{\delta y} = 0.$$  \hfill (A1)

Togetherness with (A1) an additional condition should also be satisfied at the "broken" point:

$$\left[ \frac{\partial L}{\partial y'} \right] = 0.$$  \hfill (A2)

In the case of capillary fluids, $L$ is quadratic with respect to $y'$ because $\lambda$ is constant. It implies that $y'$ is continuous at the broken point. Condition (A2) is usually called Weierstrass-Erdmann condition, or corner condition. In particular, if a piecewise $C^2$–solution $y(x)$ is constant on some interval of $x$, but is not constant on a neighboring interval, this solution should have a zero slope at the broken point.

**Appendix B: Special cases of capillary fluid motion**

1. **Isothermal motion**

   In the case of isothermal stationary motion, the whole entropy of domain $D_i$ corresponding to the bulk ($a$) and interface ($i$) is:

   $$\int_{D_i} \rho \eta dD = S_0,$$  \hfill (B1)

   where $S_0$ is constant (independent of time $t$), and $dD$ is the elementary volume. Due to constraint (B1), Hamilton’s action is modified into: there exists a constant Lagrange multiplier $T_0$ such that the new Lagrangian $L$ is associated with $a + T_0 \eta$, which is the specific free energy at constant temperature. The application of the Hamilton principle yields the same equations of motion where $a$ has to be replaced by $a - T_0 \eta$. Consequently, the specific enthalpy is replaced by the chemical potential $\mu$. The variation of $\eta$ implies $T - T_0 = 0$.

2. **Motion at constant pressure**

   In the case of stationary motion, if domain $D_i$ is an invariant control volume through which the steam flows, it verifies:

   $$\int_{D_i} dD = \mathcal{V}_0.$$  \hfill (B2)

where $\mathcal{V}_0$ is constant (independent of time $t$). Due to constraint (B2), Hamilton’s action is modified into: there exists a constant Lagrange multiplier $p_0$ such that the new Lagrangian $L$ is associated with $H = a + p_0 / \rho$, which is the specific enthalpy of capillary fluid at constant pressure $p_0$. Consequently, in Subsection IIIA in the energy equation, the specific energy should be replaced by the specific enthalpy at constant pressure $p_0$, and the equation of motion is unchanged.

**Appendix C: Isothermic oscillations of the vapor density near liquid-vapor interface ($i$)**

**FIG. 7.** If $M_i^2 < 1$, the curve $F(\rho)$ has a local maximum at $\rho_\ast \in \left[ \rho_{\text{min}}, \rho_{\text{max}} \right]$, and a local minimum at $\rho_{\text{imin}} \in \left[ \rho_{\text{max}}, +\infty \right]$. We recall that $\rho = \rho_{\text{im}}$ is a formal value of $\rho$ and that the physical part of the curve is only the red part of $F(\rho)$ corresponding to oscillations of density between $\rho_{\text{min}}$ and $\rho_{\text{max}}$.

We look for oscillating stationary vapor flow in the immediate vicinity of interface ($i$) where the temperature is $T_i$. The governing equation of motion in the vapor phase is deduced from Eqs (11)–(12), and writes in the form:

$$\lambda \frac{d^2 \rho}{dx^2} = \mu(\rho, T_i) + \frac{q_i^2}{2\rho^2} + r,$$

where $r$ is a constant of integration. The vapor is considered as an ideal gas; we get the potential $\mu$, defined up to an additive constant which can be included in $r$:

$$\mu(\rho, T_i) = c_{T_i}^2 \log \rho, \quad \text{where} \quad c_{T_i}^2 = RT_i.$$

Here $c_{T_i}$ denotes the isothermal sound velocity of vapor at temperature $T_i$. To obtain oscillatory solutions, we choose a special value of $r$ replacing it by a new constant $\rho_{\ast \ast}$:

$$\lambda \frac{d^2 \rho}{dx^2} = c_{T_i}^2 \log \left( \frac{\rho}{\rho_{\ast \ast}} \right) + \frac{q_i^2}{2\rho_{\ast \ast}^2} - \frac{q_i^2}{2\rho_{\ast \ast}}.$$  \hfill (C1)

Integrating Eq. (C1), one obtains:

$$\lambda \left( \frac{dp}{dx} \right)^2 = F(\rho) - d, \quad \text{where} \quad d = \text{const}. \hfill (C2)$$
FIG. 8. Upper figure: The vapor density oscillates near the isothermal liquid-vapor interface. At the interface the density jumps (and decreases) from \( \rho_i = 1/v_i \) to \( \rho_f = 1/v_f \). The vapor density being oscillating between two extrema \( \rho_{\text{imin}} \) and \( \rho_{\text{imax}} \) where \( \frac{d\rho}{dx} = 0 \), we have to choose between these two values. The jump from \( \rho_i \) to \( \rho_{\text{imax}} \) has a smaller amplitude compared to that from \( \rho_i \) to \( \rho_{\text{imin}} \), and hence a smaller energy decrease. Consequently, \( \frac{d^2\rho}{dx^2} < 0 \) when \( \rho_v = \rho_{\text{max}} \) and \( k = -\lambda \rho \frac{d^2\rho}{dx^2} > 0 \). Bottom figure: case of dissipative vapor flow. The oscillations of vapor density vanish near the surface boundary layer.

with

\[
F(\rho) = c_T^2 \left( \rho \log \left( \frac{\rho_{**}}{\rho} \right) - \rho + \rho_{**} \right) - \frac{q^2}{2p} \left( 1 - \frac{\rho}{\rho_{**}} \right)^2.
\]

By construction,

\[
F(\rho_{**}) = 0, \quad \frac{dF}{d\rho}(\rho_{**}) = 0.
\]

The variation of \( F \) for the Mach number \( M_i^2 = \frac{q^2}{(\rho_{**} c_T)^2} < 1 \) is shown in Figure 7. In liquid water \( \rho_l \approx 10^3 \text{kg/m}^3 \). If boiling-evaporation time of a liquid film with \( 10^{-2} \text{m} \) thickness is about \( 100 \text{s} \) then \( u \approx 10^{-4} \text{m/s} \) and for the liquid, the flow rate \( q \approx 10^{-1} \text{kg/m}^2 \text{s} \). In the vapor \( \rho_l \approx 1 \text{kg/m}^3 \) and consequently \( u \approx 10^{-1} \text{m/s} \), and \( M_i^2 \approx 10^{-7} < 1 \). It has a unique maximum point \( \rho_* \) such that \( 0 < \rho_* < \rho_{**} \). Moreover, \( F \to -\infty \) as \( \rho \to +0 \). Hence, for any \( d \) such that \( 0 < d < F(\rho_*) \) one has a solution of (C2) oscillating between \( \rho_{\text{min}} \) and \( \rho_{\text{max}} \), where \( F(\rho_{\text{min}}) = F(\rho_{\text{max}}) = d \) (see Figure 7). The solution of (C2) is schematically shown in Figure 8 on the high diagram. The liquid–vapor interface is considered as a discontinuity. So, the density jumps from \( \rho_i \) to the extreme value of the vapor density (see the extra condition (19)). Since we have two possible values (minimum and maximum values), the choice has to be done. Obviously, the jump from \( \rho_i \) to \( \rho_{\text{max}} \) has a smaller amplitude compared to that from \( \rho_i \) to \( \rho_{\text{min}} \), and hence the smallest energy variation. Also, physically, only this choice allows us to obtain ‘levitation’ of the liquid film. Such a stationary periodic solution gives us an idea about a strong density variation near the interface: the liquid-vapor interface is endowed with a microstructure representing a strongly oscillatory region. The vapor region represents a transition zone that begins with an oscillatory regime and ends with a region of homogeneous density (see the bottom diagram in Figure 8).
