Pulmonary metastases from intracranial meningioma

Sir,

Meningioma is one of the most common intracranial tumors. Most meningiomas are benign and slowly growing (WHO grade-1), however atypical (WHO grade-2) and anaplastic (WHO grade-3) meningiomas show more aggressive biological behaviour with high risk of recurrence and metastases. Here we present an unusual case of multiple pulmonary metastases from recurrent intracranial meningioma in a 30-year-old male patient.

A 30-year-old male patient presented in April 2010 with complaints of headache since 1 month and two episodes of seizures. He underwent contrast-enhanced MRI of brain [Figure 1a] which showed an extra-axial, dural-based, enhancing mass lesion with areas of necrosis and perilesional edema in right frontal lobe adjacent to falx with minimal compression over right lateral ventricle suggestive of a meningioma. Total excision of the lesion was done and post operative HPE report was of a Grade-1 meningioma (fibroblastic).
He was asymptomatic for 1 year, but developed headache and vomiting in April 2011. Plain CT scan of brain [Figure 1b] showed recurrence of lesion and total excision of the lesion was done. The post operative HPE report [Figure 1c and d] showed spindle cells arranged in fascicles with marked pleomorphism and frequent mitosis suggestive of anaplastic meningioma (Grade-3) with Ki 67 labeling index 20%. He was given adjuvant radiation therapy and was under follow up.

In August 2013, he presented with complaints of cough and chest pain. Chest radiograph [Figure 2a] was done and showed multiple round soft tissue density lesions of varying sizes (Cannon ball lesions) in both lungs. CECT chest [Figure 2b] was done and showed multiple heterogeneously enhancing lesions in both lungs diffusely. CT-guided biopsy of lung lesion was done and HPE report was metastases from meningioma [Figure 2c and d] with EMA and Vimentin were positive, P 63 was focally positive, TTF was negative and Ki 67 labeling index was 7%. Chemotherapy was started and the patient is tolerating well.

Meningiomas are one of the most commonly encountered intracranial neoplasms and represent 14% to 19% of all intracranial neoplasms.[1] They originate from Arachnoid cap cells. They usually occur between 20 and 60 years of age with a peak incidence at 45 years.

According to WHO criteria, there are three grades of histopathological subtypes of meningioma present, Grade-1 is typical meningioma, Grade-2 is atypical meningioma and Grade-3 is anaplastic (malignant) meningioma. A report by WHO indicated that 94.3% of meningiomas are benign with 5 year recurrence rate of 3% as compared to 38% and 78% for atypical and anaplastic meningiomas, respectively.[2] Metastases from benign meningiomas are rare and usually associated with large intracranial tumors.[3] However, rate of metastases from atypical and anaplastic meningiomas are up to 5% and 30%, respectively[4] [Table 1].

Histological parameters that are used as indicators for aggressive behaviour and predictors of rapid recurrence and metastases are high mitotic index, hypercellularity, loss of architecture, tumor necrosis, nuclear pleomorphism and ability for brain invasion.[5] The routes of spread for meningioma are hematogenous, lymphatic and through cerebrospinal fluid.[6] The common sites for distant metastases are lungs (60%), pleura (9%), mediastinum (5%), liver, lymph nodes and bones.[7]

Some of the interesting facts regarding the metastatic nature of meningiomas are – (a) Meningiomas of more than WHO grade-1 have the greatest tendency to metastasize,[8] (b) a high rate of cellular proliferation is not essential for extracranial metastases,[9] (c) an individual meningioma of any type may metastasize including WHO grade-1[10] and the metastasis itself may also benign, (d) the time interval from diagnosis

**Table 1:**[3–4] Incidence of post operative recurrence and distant metastasis for meningiomas

| Meningiomas      | 5-year recurrence rate (%) | Distant metastasis |
|------------------|---------------------------|-------------------|
| Benign (Gr-1)    | 3                         | Rare              |
| Atypical (Gr-2)  | 38                        | 5%                |
| Anaplastic (Gr-3)| 78                        | 30%               |

Figure 1: (a) Post contrast MRI of brain in coronal section shows a well-defined, extra-axial, dural-based, enhancing mass lesion with necrosis and perilesional edema in right frontal cortex in the parafalcine region causing a minimal mass effect over right lateral ventricle and falx. (b) Plain CT scan of brain axial image shows recurrence of the lesion. (c) H and E-stained section shows spindle cells arranged in fascicles with marked pleomorphism and frequent mitosis suggestive of anaplastic meningioma (Grade 3). (d) Ki-67 immunostaining with the MIB-1 antibody showing a labeling index of 20%

Figure 2: (a) Chest radiograph frontal view shows multiple round soft tissue density lesions of varying sizes (Cannon ball lesions) in both lungs. (b) Post contrast CT scan of chest in coronal section showing multiple heterogeneously enhancing lesions in both lungs. (c) H and E stain of lung biopsy showing replacement of lung parenchyma by lesion. (d) H and E-stained section shows spindle to polygonal cells arranged in sheets and whorls with scattered mitotic figures suggestive of metastases from meningioma
Pulmonary histoplasmosis mimicking carcinoma lung

Sir,

Human histoplasmosis is an endemic mycosis caused by a dimorphic fungus. Human histoplasmosis is an endemic pulmonary illness. However, patients with advanced AIDS usually develop progressive disseminated histoplasmosis. In a minority of cases the manifestations can mimic primary or metastatic malignancies leading to delay in appropriate treatment or unwarranted therapeutic interventions. Here we report a case of histoplasmosis which was radiologically mimicked as lung malignancy with pleural deposits.

A 70-year-old South Indian lady who was apparently normal 3 months before presented with neck pain and generalized fatigue for 2-month duration. She was conservatively managed at local hospital, but her symptoms were deteriorating with increased tiredness and occasional cough. It was associated with loss of weight and loss of appetite. There was no history of fever, dyspnea, night sweats, dysphagia and hemoptysis. She is a farmer by occupation who was actively farming until 10 years back. But she had no history of smoking or working in the mining industry. She had no history of tuberculosis or other lung disease in her family. She was afebrile and her vitals were stable. General examination revealed grade 2 clubbing and there was no pallor, icterus or generalized lymphadenopathy. There was no hepatosplenomegy. Breath sounds were decreased in the right lower zone. The rest of the respiratory examination was unremarkable. Routine blood investigations revealed hemoglobin of 12.1 gm%, total count of 10,000/cmm (neutrophils: 66.9%, lymphocytes: 21.3%, eosinophil 4.2%, monocytes: 7.2%, basophil: 0.4%) and Erythrocyte sedimentation rate of 90. Viral markers including HIV, HBsAg, and HCV were negative. Chest X-ray revealed widening of mediastinum, upper zone collapse and bilateral lower rib erosion. Contrast-enhanced CT chest was performed which revealed

In conclusion, in a patient with multiple cannon ball pulmonary lesions with a history of meningioma, especially with local recurrence, one of the differential diagnoses to be considered is metastatic meningioma.
