(Dated: August 27, 2018)

An analytical theory, based on the perturbative treatment of the disorder and extended into a self-consistent set of equations for the dynamical density correlations, is developed and applied to the prototype one-dimensional model of many-body localization. Results show a qualitative agreement with numerically obtained dynamical structure factor in the whole range of frequencies and wavevectors, as well as across the transition to the non-ergodic behavior. The theory reveals the singular nature of the one-dimensional problem, whereby on the ergodic side the dynamics is subdiffusive with dynamical conductivity \( \sigma(\omega) \propto |\omega|^{\alpha} \), i.e., with vanishing d.c. limit \( \sigma_0 = 0 \) and \( \alpha < 1 \) varying with disorder, while we get \( \alpha > 1 \) in the localized phase.

I. INTRODUCTION

Many-body localization (MBL) is a challenging phenomenon involving the interplay of disorder and particle interaction (correlations). In the fermionic systems it has been proposed as an extension of the single-particle Anderson localization\textsuperscript{1,2} remaining qualitatively valid at finite interactions\textsuperscript{3,4} and at large enough disorder even at high temperature \( T \). In contrast to normal (ergodic) systems, the MBL state should reveal vanishing d.c. transport\textsuperscript{5} as well as a nonergodic time evolution of correlation functions and of quenched initial states\textsuperscript{6,7,8,9}. The vanishing of d.c. mobility\textsuperscript{10} and the nonergodic decay of the initial density profile\textsuperscript{11,12,13,14,15,16,17,18,19,20} have been the main experimental signatures of the MBL in fermionic cold-atom systems.

The dynamical structure factor \( S(q, \omega) \) is the obvious observable to characterize the one-dimensional (1D) system undergoing the ergodic–nonergodic (MBL) transition. Theoretical studies so far concentrated mostly on the uniform (wavevector \( q \to 0 \)) response as, e.g., contained in the optical conductivity \( \sigma(\omega) \) and its d.c. limit \( \sigma_0 \). In this connection, a challenging question is the possibility of subdiffusive dynamics\textsuperscript{22,23,24} which implies vanishing d.c. transport, e.g., \( \sigma_0 = 0 \) but anomalous low-\( \omega \) dependence of the optical conductivity \( \sigma \propto |\omega|^{\alpha} \) with \( \alpha < 1 \). On the other hand, in the cold-atom experiments so far more accessible are density correlations with \( q = \pi/24_0 \) as measured via the time-dependent imbalance\textsuperscript{25,26,27,28,29,30}.

In this paper we first present results for \( S(q, \omega) \) within the prototype disordered 1D model of interacting spinless fermions, displaying the whole range of wavevectors \( q = [0, \pi] \), as obtained with a numerical calculation at \( T \to \infty \) on small finite-size systems with up to \( L = 24 \) sites. We show that it is convenient and informative to analyse the \( S(q, \omega) \) spectra in terms of memory functions, representing the corresponding dynamical conductivity \( \sigma(q, \omega) \) and even further the current decay-rate function \( \Gamma(q, \omega) \). Such quantities reveal more clearly the transition to the MBL regime, as well as the behavior in the case of subdiffusion.

We further introduce for the same model an analytical theory, based on the perturbative treatment of the current-decay function \( \Gamma(q, \omega) \) and extended to a self-consistent (SC) evaluation of density-correlation function \( \phi(q, \omega) \). The theory reveals the specific nature of the 1D problem, leading to a singular coupling between \( q \to 0 \) density and energy diffusion modes. Still, the solution of the SC equations with an additional cut-off simulating a finite system size \( L^* \) shows qualitative and at weaker disorder even quantitative agreement with numerically obtained results for \( S(q, \omega) \) and related \( \sigma(q, \omega) \). Moreover, the finite-size scaling of SC results reveals in the ergodic phase the subdiffusive dynamics, consistent with \( \sigma(\omega \to 0) \sim |\omega|^{\alpha} \) with \( \alpha < 1 \). The MBL transition at critical disorder \( W = W_c \) is thus determined by a dynamical exponent \( \alpha = 1 \), while the MBL phase is characterized by \( \alpha > 1 \) and a finite dielectric polarizability \( \chi_d \) of the insulating system.

The paper is organized as follows: In Sec. II we present the model and the general formalism for density dynamical susceptibility \( \chi(q, \omega) \), which is related to generalized dynamical conductivity \( \sigma(q, \omega) \) and further to the current decay-rate function \( \Gamma(q, \omega) \). In Sec. III we present results for \( S(q, \omega) \), obtained via numerical exact-diagonalization technique for \( T \to \infty \) on finite chains for all available \( q \). Results of \( \sigma(q, \omega) \) and \( \Gamma(q, \omega) \), obtained with help of formalism introduced in Sec. II, are also presented. This allow for connection with previous studies of, e.g., optical conductivity \( \sigma(\omega) \) and also a motivation as well as a stringent test for the proposed analytical theory. In Sec. IV we introduce analytical approximations, based on the perturbative treatment of \( \Gamma(q, \omega) \). Furthermore, with some additional simplifications, solution for \( \Gamma(q, \omega) \) is extended into a SC set of equations. Numerical results of these equations are presented and commented in Sec. V. Besides the qualitative agreement with finite-size results, we put the emphasis on the low-\( \omega \) regime where the SC equations appear to be singular in 1D. Scaling an effective chain length \( L^* \) we show that in the ergodic regime the solutions are consistent with an interpretation in terms of a subdiffusion phenomenon. Conclusions, critical reflections on the method and results are given in Sec. VI.
II. DYNAMICAL DENSITY CORRELATIONS

We consider the prototype (standard) model of MBL, the 1D system of interacting spinless fermions with random local potentials,

\[ H = -t \sum_i \left( c_i^\dagger c_i + \text{H.c.} \right) + V \sum_i n_{i+1} n_i + \sum_i \epsilon_i n_i. \]

As usual, we assume quenched disorder with the uniform distribution \(-W < \epsilon_i < W\) and in the numerical analysis the system at half-filling, i.e., \(\bar{n} = 1/2\). We further-on use \(t = 1\) as the unit of energy. While most numerical results so far are for \(V = 2\) (corresponding to isotropic Heisenberg model\([6,8,12]\)), we use for the demonstration \(V = 1\) enabling closer comparison with the analytical theory. Since \(T\) should not play an essential role in the MBL problem, studies are adapted to the limit \(\beta = 1/T \to 0\), which simplifies the analytical as well as the numerical approach.

Our analysis deals with dynamics of the density operator

\[ n_q = \frac{1}{\sqrt{L}} \sum_i e^{iqi} n_i. \]

at arbitrary wavevector \(q\), as defined by the dynamical susceptibility \(\chi(q, \omega)\), and related relaxation function \(\phi(q, \omega)\),

\[ \chi(q, \omega) = i \int_0^\infty d\tau e^{i\omega\tau} \langle [n_q(\tau), n_{-q}] \rangle, \]

\[ \phi(q, \omega) = \frac{1}{\omega} [\chi(q, \omega) - \chi^0(q)], \]

with its static (thermodynamic) value \(\chi^0(q)\) (see formal background and definitions in Appendix A), which in normal ergodic systems satisfies \(\chi^0(q) = \chi(q, \omega \to 0)\).

In a homogeneous system \((..)\) denotes the canonical thermodynamical average. In a disordered system we perform in addition the averaging over all random configurations of \(\epsilon_i\). We have to stress that \(n_q\) is a macroscopic operator (not a local one), and in the following analysis we study only such quantities. This implies that dynamical correlations functions, as defined by Eq. [5], are expected to be self-averaging, i.e., the configuration averaging is in principle not required in the macroscopic limit of \(L \to \infty\). Here, we rely on a similarity with the treatment of Anderson localization of NI electrons\([11,12]\) as well on recent analysis of sample-to-sample fluctuations of \(\sigma(\omega)\) in the same MBL model\([12]\). Nevertheless, this aspect has still to be critically examined when taking the limit \(\omega \to 0\) since the fluctuations at larger disorder can be singular (referred in 1D as the Griffiths effect of rare but large random deviations\([13,14]\). In particular, this is the relevant question within the nonergodic (MBL) phase.

The advantage of above formulations is that it remains meaningful even in nonergodic cases where \(\chi^0(q) > \chi(q, \omega \to 0)\)\([13,14]\), as expected within the MBL regime. It is helpful to represent and analyse \(\phi(q, \omega)\) in terms of complex memory functions\([15]\) (see formal derivation and relations in Appendix B),

\[ \phi(q, \omega) = \frac{-\chi^0(q)}{\omega + M(q, \omega)}, \]

\[ M(q, \omega) = i \frac{g_q^2}{\chi^0(q)} \sigma(q, \omega), \]

related to the \(q\)-dependent conductivity \(\sigma(q, \omega)\) via the continuity equation \([H, n_q] = g_q j_q\), where \(g_q = 2 \sin(q/2)\) and \(j_q\) is the current operator for given \(q\). It should be noted that \(\sigma(q, \omega)\) has the usual meaning only in the limit \(q \to 0\), where \(\sigma(\omega) = \text{Re} \sigma(q \to 0, \omega)\) is the optical conductivity. We make a further step and define the current relaxation-rate function \(\Gamma(q, \omega)\) as

\[ \sigma(q, \omega) = \frac{i \chi^0(q)}{\omega + \Gamma(q, \omega)}, \]

where \(\chi^0(q)\) is the static current susceptibility. We note that \(\gamma(\omega) = \text{Im} \Gamma(q, \omega)\) is \((\beta \to 0)\) independent of \(\beta\) and has the meaning of the effective current relaxation rate at \(\omega \to 0\).

The limit \(\beta \to 0\) allows also for analytical evaluation of static quantities, in particular,

\[ \chi^0(q) = \beta \bar{n}(1 - \bar{n}) = \chi^0, \]

(5)

\[ \chi^0(q) = \beta 2 t^2 \bar{n}(1 - \bar{n}) = \chi^0. \]

With known static quantities, Eq. [4], the relation between \(\phi(q, \omega)\) and, e.g., \(\Gamma(q, \omega)\) is thus unique and exact (not depending on approximations introduced later-on), and can be used in any direction provided that one of both quantities is evaluated. It is worth mentioning that Eq. [4] together with Eq. [5] resemble continued fraction expansion of frequency moments of complex correlation functions. Such a approach was recently used in Ref. [37] to numerically evaluate optical conductivity \(\sigma(\omega)\) in strong disorder limit. Here, we develop analytical theory for first three moments of such a series (see Section IV).

III. NUMERICAL FINITE-SIZE RESULTS

We note the relation of above quantities to standard dynamical structure factor \(S(q, \omega)\), which is at \(\beta \to 0\) given by

\[ \text{Im} \phi(q, \omega) = \pi \beta S(q, \omega). \]

(7)

Before introducing the analytical method, we comment on numerical finite-size results, which serve later-on as a test for the proposed analytical theory. The dynamical quantity calculated directly is \(S(q, \omega)\), whereby we employ the microcanonical Lanczos method (MCLM) on finite systems at \(\beta \to \infty\). In Fig. [1] we present characteristic results for \(S(q, \omega)\) for \(L = 24, V = 1, W = 0, 2, 4\) in the whole range of wavevectors \(q = [0, \pi]\). They already allow for some rough distinction of dynamical density correlations in three regimes: (a) At \(W = 0\) \(S(q, \omega)\) is the response of the homogeneous 1D chain of interacting spinless fermions. Due to integrability of such a model, even at \(\beta \to 0\) the response has close analogy to
non-interacting (NI) fermions (i.e., at $V = 0$). In particular, the $S(q, \omega)$ has no diffusion pole and is quite featureless (at $\beta \to 0$ in the interval $\omega < 4 \sin(q/2)$). (b) At weak disorder $0 < W = 2 < W_c \sim 3.5^{[19]}$, an additional feature is a diffusion (or diffusion-like, as discussed later-on in relation to subdiffusion) pole which has a finite width $\delta \omega \propto q^2$ and is well visible at small $q \ll \pi/2$. (c) For large disorder $W = 4 > W_c$ the response becomes singular at all $q$ and $S(q, \omega \to 0) \to S(q,\omega)$ shows a finite stiffness $S_q > 0$, being a hallmark of MBL regime.

Since $S(q, \omega)$ is quite singular function (at least for $q \to 0$), it is helpful to extract the corresponding $\sigma(q, \omega)$ and $\Gamma(q, \omega)$ via Eqs. 4, 5. To this purpose we first calculate complex $\delta(q, \omega)$ from $S(q, \omega)$. Next, with known $\chi^0, \chi^1$ we evaluate $\sigma(q, \omega)$ and $\Gamma(q, \omega)$. In the numerical procedure it is crucial to have high frequency $\omega$ resolution of MCLM results, which are obtained by employing $N_L \sim 10^4$ Lanczos steps in order to get $\delta \omega \lesssim 0.003$ of $S(q, \omega)$ spectra.

Characteristic results obtained for $L = 24$ and averaged over $N_s \sim 100$ random configurations are presented in Fig. 3. Some generic features be inferred: (a) Consistent with previous calculations of $\sigma(\omega)$, our results indicate (for all disorders $W$) the maximum at $\omega = \omega^* > 0$, and more important a nonanalytical low-$\omega$ behavior, i.e., $\sigma(\omega) \sim \sigma_0 + \xi(\omega)^\alpha$. Here our numerical results in the ergodic regime, $W < W_c$, imply an interpretation with $\sigma_0 > 0$ and $\alpha \sim 0.2$, while we comment later-on the possibility of the subdiffusion with $\sigma_0 = 0$ and $\alpha < 0.2$. (b) Within our resolution $\sigma_0$, but also general $\sigma(q, \omega \to 0)$, vanishes for $W \geq W_c$ consistent with the onset of the MBL phase and nonergodicity at all $q$. This implies necessarily via $\text{Eq. } 5$ a divergent $\gamma(q, \omega \to 0) \to \infty$, as also evident on approaching the MBL transition.

For comparison we present in Fig. 4 also corresponding numerical results for $V = 2$, which corresponds to the isotropic Heisenberg model with random magnetic fields and has been in this connection studied more frequently. One can notice that larger $V$ does not change qualitatively results for both $\sigma(q, \omega)$ as well as $\gamma(q, \omega)$, but rather additionally broadens spectra, except the MBL singularity at $\omega \sim 0$ for $W = 2$.

IV. ANALYTICAL APPROACH TO CURRENT DECAY-RATE FUNCTION

A. Effective force

The motivation for following analytical approach and approximations comes form the perturbation theory, which can be performed for weak disorder $W \to 0$ (and somewhat more delicate for $V \to 0$) on the level of the current decay-rate function $\Gamma(q, \omega)$, in analogy to the theory of current scattering mechanisms in simple metals. Such a theory has been extended to the nontrivial problem of Anderson localization by taking it beyond the perturbative approximation and we will partly follow an analogous treatment for the MBL problem.

The expression for $\Gamma(q, \omega)$ (see the formal derivation and
Eq. (30) in the Appendix B) is the starting point for the analytical approximations. The current scattering mechanism is determined by the operator for the effective force \( F_q = Q \mathcal{L} j_q \), with the Liouville operator \( \mathcal{L} j_q = [H, j_q] \) and \( Q \) representing the operator \( j_q \) which projects into space perpendicular to \( n_q \) (see Appendix B for details). \( \mathcal{L} j_q \) can be evaluated explicitly from the model \( I \),

\[
\mathcal{L} j_q = t g_q h^d_q - \frac{1}{\sqrt{L}} \sum_k g_k \epsilon_k h^k_{q-k} - \frac{V}{\sqrt{L}} \sum_k w_k n_k h^k_{q-k} + 2 t^2 g_q n_q ,
\]

where \( w_k = 2 \sin(3 k/2) \) and we define also (Fourier transforms of) kinetic-energy, potential and next–nearest hopping terms, respectively,

\[
h^k_q = - \frac{t}{\sqrt{L}} \sum_i e^{q(i+1/2) [c^\dagger_{i+1} c_i + H.c.]},
\]

\[
h^d_q = - \frac{t}{\sqrt{L}} \sum_i e^{q [c^\dagger_{i+1} c_{i-1} + H.c.]},
\]

\[
\epsilon_k = \frac{1}{\sqrt{L}} \sum_i e^{q i} \epsilon_i .
\]

In the evaluation of \( F_q \) the last term in Eq. (8) vanishes due to \( Q n_q = 0 \). Other three terms remain unaffected by the action of \( Q \) within \( \beta \rightarrow 0 \) limit. With such a force operator \( F_q \) we can write

\[
\Gamma(q,\omega) = \frac{1}{\chi_j} \Lambda(q,\omega) ,
\]

\[
\Lambda(q,\omega) \sim \frac{\chi_F(q,\omega) - \chi^0_F(q)}{\omega} ,
\]

where \( \chi_F(q,\omega) \) are the generalized (force) susceptibilities, defined for the operator \( F_q \) [compare with Eq. (3)]. In the above expression, in analogy to weak scattering theory [the NI limit (but with disorder \( \delta = W/\sqrt{3} \), corresponding to the width of the random-potential distribution. This detail hardly influence any qualitative results further-on, since \( \Gamma_1(q,\omega) \) does not contribute in the hydrodynamic regime \( q \rightarrow 0 \).]

By decoupling the static disorder and dynamical density fluctuations in \( \Gamma_2(q,\omega) \), we get

\[
\Lambda_2(q,\omega) = \frac{1}{L} \sum_k g_{q-k}^2 (\epsilon_{k-q}^2 \phi_k(k,\omega) ,
\]

where \( \phi_k(q) \) is the relaxation function of the kinetic-energy \( h^k_q \), Eq. (9), defined in analogy to \( \phi(q,\omega) \), Eq. (3). In the NI limit (but with disorder \( W > 0 \)) Eq. (12) reduces to

\[
\Gamma_2(q,\omega) = \frac{W^2}{6 t^2 L^2} \sum_{k,k'} \frac{g_{k-q}^2 \epsilon_{k-q}^2}{\omega + \epsilon_{k+k'}/2 - \epsilon_{k-k'}/2} ,
\]

which is the lowest-order scattering (Boltzmann-type) result [11], in particular it gives a finite relaxation rate \( \gamma(q,\omega) = \text{Im} \Gamma(q,\omega) \), also in the hydrodynamic \( (q,\omega) \rightarrow 0 \) limit.
The perturbative treatment of the interaction term is more problematic. One can assume that the dynamical fluctuations of density $n_k$ and kinetic energy $h_k^{q-k}$ are independent, which leads to

$$\text{Im } \Lambda_3(q, \omega) = \frac{V^2}{L} \sum_k \frac{w_k^2}{\pi \beta} \int_{-\infty}^{\infty} \text{d}\omega' \times \text{Im } \phi(k, \omega') \text{Im } \phi_k(q - k, \omega - \omega') \quad (14).$$

When we insert the NI input for $\phi(q, \omega)$ and $\phi_k(q, \omega)$, the interaction $V > 0$ leads to additional current decay channel, even at $(q, \omega) = 0$. While this is an effect generally expected from the inter-particle interaction, in our particular case it is not fully justified since the pure ($W = 0$) model is integrable and exhibits a dissipationless current and singular $\sigma(\omega \sim 0) = \beta D\delta(\omega)$ with $D > 0$ even at $\beta \rightarrow 0$. Since we are interested more in the role of disorder and of a generic interaction term, where current dissipation should emerge from a term like Eq. (14), we would here stay at this level of approximation.

C. Self-consistent closure

At this stage we are not aiming to develop more detailed theory for kinetic-energy fluctuations $\phi_k(q, \omega)$ entering Eqs. (13),(14). It is, however, crucial to take into account the fact that the kinetic-energy function has an overlap with the energy-density relaxation function. In a disordered system, the energy is, besides the number of particles, the only conserved quantity. It is therefore essential to take properly the energy is, besides the number of particles, the only conserved quantity. It is therefore essential to take properly the energy fluctuations, and we treat these correlations in analogy to Eqs. (4),(5) with the role of $\phi(q, \omega)$ replaced by the thermal conductivity $\kappa(q, \omega)$. The latter has been found to have similar behavior close to the MBL transition, in particular the vanishing of d.c. value $\kappa_0$ and anomalous low-$\omega$ behavior. Taking into account sum rules $\eta = \chi_k^0/\chi_0 = 2t^2$ we further-on work with a simplification $\phi_k(q, \omega) = \eta \phi(q, \omega)$ representing an effective Wiedemann-Franz relation, i.e., assuming the same relaxation rates for density and energy currents.

Since $\Lambda \propto \phi \propto \beta$, we further-on work with renormalized relaxation functions, i.e., $\bar{\phi} = \phi/\chi_0$, $\bar{\kappa} = \phi_k/\chi_0$. So the final SC equations, besides $\Gamma_1(q, \omega)$, where we do not correct Eq. (11), are

$$\Gamma_2(q, \omega) = \frac{\eta W^2}{6 t^2 L} \sum_k \bar{g}_k^2 \bar{\phi}(k, \omega), \quad (15)$$

$$\text{Im } \Gamma_3(q, \omega) = \frac{\eta \bar{n} W^2}{2 \pi L} \sum_k \frac{w_k^2}{\pi \beta} \int \text{d}\omega' \text{Im } \bar{\phi}(k, \omega') \times \text{Im } \bar{\phi}(q - k, \omega - \omega'), \quad (16)$$

where $\bar{n} = \bar{n}(1 - \bar{n})$. The MBL physics, in particular the transition, is predominantly governed by $\Gamma_2(q, \omega)$, while for $W > 0$ the interaction-driven term $\Gamma_3(q, \omega)$, due to convolutions in $(q, \omega)$, yields rather a featureless function, leading to the current decay at all $q$.

Due to the coupling to the $q \rightarrow 0$ diffusion mode in Eq. (11), it is evident that $\Gamma(q, \omega \rightarrow 0)$ as well as the whole SC set might be singular in 1D. In order to simulate finite-size systems (as studied numerically) and explore the finite-size scaling we introduce a finite cutoff $k_m = \pi/L^*$, in particular in Eq. (15). It should be pointed out that after taking mentioned simplifications there are (at given model constants $V, W$) no free parameters in the SC theory apart from the cutoff $k_m$ (effective length $L^*$).

We note that presented SC equations have an analogy to simplified theories of Anderson localization$^{[2]}$. It has been, however, established that proper SC localization theory for NI fermions$^{[22]}$ should take into account the time-reversal symmetry of correlation functions on a single-particle level. The latter is, however, lost by including finite interaction $V > 0$. As a consequence, Eq. (15) emerges as a nontrivial coupling of only remaining low-$\omega$ collective modes in the system, i.e., the density and the energy diffusion mode.

V. NUMERICAL SOLUTIONS OF SC EQUATIONS

A. General features

Having SC set of equations, Eqs. (4),(5),(11),(15),(16), it is straightforward to find solutions by numerical iteration of coupled equations until convergence, whereby we use at the initial step the NI input for $\phi(q, \omega)$. In Fig. 2 we present typical SC-theory results for $\Re \sigma(q, \omega)$ and $\gamma(q, \omega)$ along with the MCLM numerical ones, whereby we use $L^* = 24$ corresponding to the size used in MCLM calculation. Qualitative agreement is quite satisfactory for modest value of disorder strength $W$, in particular the analytical theory reproduces some essential features: (a) Maxima of $\sigma(q, \omega)$ with $\omega^* > 0$ emerge also in SC solutions due to a nontrivial maxima in $\gamma(q, \omega \rightarrow 0)$. The maximum moves towards $\omega^* \sim 0$ for weaker disorder $W < 0.8$, which would be the signature of a normal diffusion. (b) In the ergodic regime at $W < W^*_c \sim 1.6$ low-$\omega$ SC results for small $L^* < 100$ can be roughly fitted to $\sigma(\omega) = \sigma_0 + b|\omega|^\alpha$ with $\sigma_0 > 0$ and $\alpha \sim 1$ close to the MBL transition. (c) Due to a large increase of $\gamma(q, \omega \rightarrow 0)$ the conductance $\sigma(q, \omega \rightarrow 0)$ is strongly reduced for larger $W > 1$. (d) Eventually, for $W > W^*_c$ the SC equations yield a singular solution $\gamma(q, \omega \sim 0) = \gamma_s \delta(\omega)$ which is the hallmark of the nonergodicity and leads also to vanishing d.c. transport $\sigma(q, \omega \rightarrow 0) = 0$.

The behavior with $W$ varying across the MBL transition is presented in Fig. 4 where we compare results for disorder strength up to $W = 4 \gg W^*_c$. We observe that the quantitative agreement between SC and numerical result is steadily decreasing with increasing $W > W^*_c$. This coincides with the fact that SC threshold $W^*_c \sim 1.6$ is significantly below numerical (at $V = 1$) estimate $W_c \sim 3.10$. The origin of this discrepancy in critical $W^*_c$ can traced back to overestimated coupling between density and energy diffusion mode enhancing the feedback (localization) mechanism in SC equations via the $\gamma(q, \omega \rightarrow 0)$ behaviour. Still, the overall qualitative change across the MBL transition follows the same pattern as
the numerical one.

Figure 4. (Color online) Comparison between SC and numerical (MCLM) results of (a) $\text{Re}\sigma(q, \omega)$ and (b) $\gamma(q, \omega)$ for $q = \pi/12$, $L = L^* = 24$, and various disorder strengths $W = 1, 2, 3, 4$.

When we are comparing SC results for optical conductivity $\sigma(\omega) = \sigma(q \to 0, \omega)$ with previous numerical studies (as well as this study for $q > 0$) on finite systems, we should use appropriate $L^*$ as well as corresponding $\delta\omega$. In Fig. 5 we present a characteristic result for modest $L^* = 40$ (and $\delta\omega \sim 10^{-3}$) for $\sigma(\omega)$ across the transition to the MBL, i.e. $1.2 \leq W \leq 2.0$, together with the low-$\omega$ fit $\bar{\sigma}(\omega) = a + b|\omega|^c$. We note that such a fit should be evidently restricted to the range well below the maximum $\omega \ll \omega^*$ which is for $W > W^*_c$ at $\omega^* \sim 1$, but for lowest $W = 1.2$ moves down to $\omega^* \sim 0.1$. Nevertheless, the overall behavior around the transition $W \sim W^*_c$ is characterized by $\alpha \sim 1$ and a clear drop of $\sigma_0$.

Figure 5. (Color online) Comparison of SC solution (solid line, $L^* = 40, \delta\omega = 10^{-3}$) with the fit $\bar{\sigma}(\omega) = a + b|\omega|^c$ (dashed line), with $c = 0.8, 1.0, 1.5$ for $W = 1.2, 1.6, 2.0$, respectively.

B. Subdiffusion and transition to MBL

While SC results in Fig. 3 (as well as Fig. 5) show an overall behavior for $W < W^*_c$ and $W \sim W^*_c$, consistent with numerical results at finite $L^*$, we further investigate in more detail the consequences of the singular aspects due to 1D. In order to explore the low-$\omega$ behavior, we concentrate on most interesting $q \to 0$ results and present in Fig. 6 $\sigma(\omega)$ as obtained with large frequency $\omega$ resolution ($\delta\omega \sim 10^{-4}$) at several characteristic $W$ and varying effective length $L^* = 20 - 320$. It should be realized that the choice of $\delta\omega$ in the numerical SC procedure is intimately related to $L^*$ and we cannot get strictly $\sigma_0 = 0$ at $\delta\omega > 0$. Nevertheless the scaling $\delta\omega \to 0$, as shown in the inset of Fig. 6 is consistent with vanishing $\sigma_0 = 0$, at least for $W > 1.2$. This is also presented in Fig. 7 which depicts dependence of dynamical conductivity $\text{Re}\sigma(q, \omega)$ on frequency resolution, $\delta\omega$, for fixed cutoff $L^* = 20$ and $L^* = 640$ and various disorder strength.

Taking this into account, we can distinguish three regimes as already noted in numerical studies (30,26). (a) At small disorder $W < 1\sigma(\omega \to 0)$ is only weakly dependent on $L^*$ and it is hard to detect signatures of a subdiffusion even at extreme $L^* \gg 100$. (b) At the intermediate $1 < W < W^*_c$ we confirm the steady decrease of $\sigma_0$ with increasing $L^*$ and the behavior can be well captured with subdiffusion form $\sigma(\omega) \propto |\omega|^\alpha$ with $\alpha < 1$. (c) For $W > W^*_c$ results become again only weakly $L^*$ dependent, while the d.c. value $\sigma_0$ is vanishing.

To make the analysis of subdiffusion more objective, we define the exponent via the maximum slope

$$\alpha = \frac{d \log \sigma(\omega)}{d \log \omega},$$

in the range $\omega < 0.1$. Results are shown in Fig. 8a. It is indicative that the subdiffusion with $\alpha \ll 1$ can be hardly established for $W < 1$ since it requires $L^* \gg 10^{10}$. On the other hand, results with $\alpha > 0.3$ are better resolved. The crossing $\alpha = 1$ marks the MBL transition to the nonergodic
phase, where for large \( W \gg W^* \) we get \( \alpha \sim 2 \), as expected deep inside the localized regime.\(^2\)

As an uniform \((q \to 0)\) order parameter within the MBL (nonergodic) phase one can consider the current-relaxation stiffness \( \gamma_\sigma(q) > 0 \). More physical is the dielectric polarizability

\[
\chi_d = \frac{2}{\pi} \int_0^\infty \frac{\sigma(\omega)}{\omega^2} d\omega, \tag{18}
\]

whereby \( \chi_d < \infty \) implies that the system is dielectric, i.e., an external field along the chain induces only a finite polarizability. It is evident, that \( \alpha > 1 \) is required for \( \chi_d < \infty \). In Fig. 8b we present results for the inverse \( 1/\chi_d \) vs. \( W \) as evaluated for different \( L^* \), revealing indeed its vanishing below the MBL transition.

VI. CONCLUSIONS

Presented analytical theory is a SC extension of the perturbative evaluation of the current decay-rate function \( \Gamma(q, \omega) \). The disorder effect is reproduced within the lowest order (Boltzmann-type) scattering, while the interaction is treated only within a decoupling approximation. In analogy to the SC theory of the single-particle Anderson localization,\(^31\)\(^32\)\(^33\)\(^34\)\(^35\) the theory is closed beyond the weak scattering approximation, where the crucial assumption (at the present level of the theory) is that density and energy dynamical correlations are related, in particular at small \((q, \omega)\), and both simultaneously undergo a MBL transition.

Although the theory starts from the lowest-order calculation of the current-relaxation function \( \Gamma(q, \omega) \) its extention into a SC scheme goes well beyond the perturbative approach. A SC determination of \( \Gamma(q, \omega) \) leads, on approaching the MBL transition, to enhanced low-\(\omega\) density and energy-density fluctuations, which finally leads to the freezing of the low-\(\omega\) dynamics at the \( W = W^*_c \). Beyond this disorder correlation functions are nonergodic and characterized by singular contribution in \( S(q,\omega) \sim S_0 \delta(\omega) \) with \( S_0 > 0 \). One might question the particular validity and the form of the SC loop, however the freezing of low-\(\omega\) dynamics is well visible in numerical results and consistent with analogous phenomenon in the theory of Anderson localization.\(^36\)

In the presented theory there are no free parameters except the cutoff \( k_m = \pi/L^* \) which simulates the finite-size system and allows for the finite-size scaling. The importance of cutoff and corresponding sensitivity of SC solutions on the frequency resolution \( \delta\omega \) appears to be a singular property of 1D and makes the proper convergence of solutions of coupled analytical equations nontrivial. In spite of simplifications the presented SC theory yields several nontrivial conclusions, consistent with numerical results obtained in this paper via the MCLM method, but also with previous numerical investigations on finite systems:

(a) When simulating numerically reachable finite-size systems by taking cutoff \( L^* \sim 20 - 40 \) (as well corresponding finite-frequency resolution \( \delta\omega \sim 10^{-3} \)) our SC solutions appear to be consistent with the dynamical conductivity \( \sigma(\omega) \sim \sigma_0 + b|\omega|^\alpha \) with \( \alpha \sim 1 \) and vanishing \( \sigma_0 \) near the MBL transition.\(^26\)\(^27\)

(b) However, careful scaling beyond \( L^* > 100 \) and \( \delta\omega \ll 10^3 \) of SC solution indicates on vanishing \( \sigma_0 \) in the ergodic regime \( W < W^*_c \) (at least for \( W > 1.2 \) at \( V = 1 \)). Within the present SC theory this emerges due to the disorder-induced coupling between the density and the energy diffusion mode. As a consequence of 1D, in the ergodic regime the transport is subdiffusive, i.e., for large enough systems d.c. transport coefficients are expected to vanish, e.g., \( \sigma_0 \to 0 \). Still, for modest disorder \( W \) effective size to detect such anomalies could be huge, e.g., \( L^* \gg 10 \), and therefore hard to detect in numerical and even experimental studies.
(c) The transition to the nonergodic MBL regime $W > W_c$ appears in the theory via the onset of the current-decay stiffness $\gamma_a > 0$, which coincides with the condition for the dynamical exponent $\alpha > 1$ and the dielectric polarizability $\chi_d < \infty$.

(e) Theoretical results for dynamical correlations show an overall qualitative agreement with numerical ones (at corresponding effective length $L^*$) in the whole $(q, \omega)$ range.

When we discuss the validity and restrictions within the presented theory, there are several aspects in which should be considered:

(a) Since the theory is an extension of the perturbative treatment of disorder starting at modest $W$, it is plausible that we cannot claim a quantitative agreement for larger disorder with $W > W^*$. The reason is mainly twofold: At $W > 3$ single-particle states are already well localized. Still, more problematic seems to be the overestimated coupling between density and energy diffusion modes, which leads to overestimated feedback in SC equation and consequently to the transition at critical $W^*$, substantially smaller than emerging from numerical studies (e.g. at $V = 1$ $W^* \sim 1.6$ instead of numerical estimate $W_3 = 3$). This can be improved by taking both relevant hydrodynamic modes, i.e., density and energy diffusion, on equal footing into the analysis. In this work we skip this aspect in order to make our SC theory as transparent as possible.

(b) The current decay-rate due to interaction $V > 0$ is taken very crudely, in particular since the actual model without disorder (at $W = 0$) is integrable and $V > 0$ itself does lead to d.c. conductivity $\sigma_0 < \infty$. Nevertheless, generic interaction term is expected to lead to the scattering of d.c. current (at $T \gg 0$). Moreover $\Gamma_3(q, \omega)$ seems to be less critical dependent on dimensionality of the system, as appears the case for $\Gamma_2(q, \omega)$ emerging from disorder.

(c) The assumption that the dynamical quantities are self-averaging is inherent in the SC approach, although this aspect should be further critically examined due to possible role of rare large disorder fluctuations.$^{32}$

The presented SC scheme is more generic and can be generalized into different directions. Analogous treatment of higher dimension in rather straightforward, especially since some anomalies as, e.g., the subdiffusion are not expected there, at least not to such extent. One could treat also separately the density and energy dynamical correlations, whereby the latter one are much less investigated so far. On the other hand, for experiments on MBL in cold-atom systems$^{22,24}$ the relevant model is the disordered Hubbard model which does reveal a disorder-induced spin-charge separation$^{43}$, which might also be approached in a similar way.

APPENDIX A: CORRELATION FUNCTIONS

Since the system under consideration can be nonergodic, one should be careful with the definitions of correlation and response functions. In our analysis we define the dynamical susceptibility (response functions) $\chi_A(\omega)$ and corresponding static (thermodynamic) response $\chi_A^0$, for arbitrary operators $A$ in the standard way,

$$\chi_A(\omega) = -i \int_0^\infty dt \, e^{i\omega t} \langle [A^\dagger(t), A] \rangle$$

$$\chi_A^0 = \int_0^\beta d\tau \langle A^\dagger A(i\tau) \rangle = \langle A|A \rangle$$

where $\omega^+ = \omega + i\delta$ with $\delta \to 0$ and $\beta = 1/T$. Eq. (20) introduces the scalar product$^{33,34}$ convenient for formal representation and derivation of memory functions, even for non-ergodic systems. Above (...) denotes the canonical thermodynamical average and in a disordered system additional averaging over all random configurations of $\epsilon_i$ (see the comment in the main text after Eq. (3)).

In the analysis, instead of susceptibilities $\chi_A(\omega)$, we mostly use related relaxation functions,

$$\phi_A(\omega) = \frac{\chi_A(\omega) - \chi_A^0}{\omega} = \langle A| \frac{1}{E - \omega} |A \rangle$$

where the second representation in Eq. (21) in terms of the resolvent with Liouville operator $\mathcal{L}A = [H, A]$ is a standard one allowing formal steps further-on. The nonergodic behavior is in this framework characterized by the behavior $\chi_A^0 > \chi_A(\omega \to 0)$ leading to a singular low-$\omega$ contribution.$^{33,34,45}$

Im $\phi_A(\omega \sim 0) = \pi D_A \delta(\omega)$, \hspace{1cm} $D_A = \chi_A^0 - \chi_A(\omega \to 0)$

where $D_A$ is the corresponding stiffness.

Finally, since we are dealing only with the case of high-$T$, i.e. $\beta \to 0$, there are convenient simplification following from Eq. (20) and Eq. (21)

$$\chi_A^0 = \beta \langle A^\dagger A \rangle, \hspace{1cm} \phi_A(\omega) = -i\beta \int_0^\infty dt \, e^{i\omega t} \langle A^\dagger(t)A \rangle$$

and in particular simplified relation to the general dynamical structure factor Im $\phi(\omega) = \pi \beta S_A(\omega)$.

APPENDIX B: MEMORY-FUNCTION REPRESENTATION

We use definitions above for several operators $A$ of interest. The starting point are density relaxation function with $A = n_q$. The memory function (MF) representation of $\phi(q, \omega)$ follows from the continuity equation,

$$\mathcal{L}n_q = g_q \dot{j}_q, \hspace{1cm} \dot{j}_q = \frac{t}{\sqrt{L}} \sum_i e^{i(q+1/2)(u_{i+1}^{\dagger}c_i + \text{H.c.})}$$

(24)
where \( q_0 = 2 \sin(q/2) \). By defining the projection projector \( P \) and its complement \( Q \),

\[
P = |q_0| \frac{1}{\chi^0(q)} (q_0), \quad Q = 1 - P ,
\]

(25)

where \( \chi^0(q) = (q_0 | q_0) \), we can express relaxation function, Eq. (21), in the form of MF representation

\[
\phi(q, \omega) = \frac{-\chi^0(q)}{\omega + v^2_q \sigma(q, \omega)/\chi^0(q)} ,
\]

(26)

with

\[
\sigma(q, \omega) = (Q | j_q | Q) = \frac{1}{L_Q - \omega} (Q | j_q | Q) ,
\]

(27)

where \( L_Q = Q L_Q \) is projected Liouville operator and \( Q | j_q | Q \) by symmetry. It should be noted that \( \sigma(q, \omega) \) is in general not equal to standard conductivity \( \sigma(q, \omega) \), evaluated directly replacing in Eq. (27) the reduced dynamics with the full one, \( L_Q \to L \). Still, both quantities merge in the hydrodynamic limit \( q \to (34) \).

In the next step we express \( \sigma(q, \omega) \) in terms of the current relaxation-rate function \( \Gamma(q, \omega) \),

\[
\sigma(q, \omega) = \frac{1}{\omega + \Gamma(q, \omega)} ,
\]

(28)

where \( \chi^0(q) = (j_q | j_q) \). While such a possibility follows directly from the analytical properties of \( \phi(q, \omega) \) and \( \sigma(q, \omega) \), the formal expression (used further-on as the starting point for analytical approximations in Sec. IV) can be given, introducing additional projector

\[
P' = |j_q| \frac{1}{\chi^0(q)} (j_q), \quad Q' = 1 - P' ,
\]

(29)

so that

\[
\Gamma(q, \omega) = \frac{1}{\chi^0(q)} (F_q - \frac{1}{L_Q q'} \frac{1}{\omega} (F_q) = \frac{1}{\chi^0(q)} \Lambda(q, \omega) ,
\]

(30)

where (formally) \( L_Q q' = Q' L_Q q' \) and

\[
F_q = Q' L_q j_q = Q L_q j_q .
