Abstract

Kinetic aspect of Landauer’s blowtorch effect is investigated for a model double-well potential with localized heating. Using the supersymmetric approach, we derive an approximate analytical expression for the equilibration rate as function of the strength, width and the position of the hot zone, and the barrier height. We find that the presence of the hot zone enhances the equilibration rate, which is found to be an increasing function of the strength and width of the hot zone. Our calculations also reveal an intriguing result, namely, that placing the hot zone away from the top of the potential barrier enhances the rate more than when it is placed close to it. A physically plausible explanation for this is attempted. The above analytical results are borne out by detailed numerical solution of the associated Smoluchowski equation for the inhomogeneous medium.

1 Introduction

In a now influential paper \cite{1} on the relative stability, \textit{i.e.}, relative occupation, of the competing local energy minima for a system far from equilibrium, Landauer pointed out the globally determining role played by the non-equilibrium kinetics of the unstable intermediate states even as these are very rarely populated. More specifically, for the case of two local energy minima, \textit{i.e.}, a bistable potential, he showed that the application of a localized heating at a point on the reaction coordinate lying between the lower energy minimum and the potential barrier maximum can raise the relative population of the higher lying energy minimum over that given by the thermal Boltzmann factor $\exp(-\Delta E/k_B T)$. This is the so called ‘blowtorch’ effect \cite{1} associated with a nonuniform thermal bath. It generalizes
the problem of escape of a Brownian particle over a potential barrier under the influence of equilibrium thermal fluctuations, studied originally by Kramers [2-4], to the case of nonuniform temperature along the reaction coordinate. Later, in a related context, it has been shown that a state-dependent diffusion coefficient can produce maxima in the probability distribution at points which are not the potential minima [5-7].

A decade later, van Kampen [8] derived an equation appropriate for the description of diffusion in an inhomogeneous medium where he developed a stochastic treatment for the case of non-uniform temperature. Apart from justifying Landauer’s conjecture, he also showed that there could be a net current when the particles are allowed to diffuse back through an alternate route bypassing the hot zone. The problem has also been treated by Büttiker around the same time [9]. He showed that a net current is possible, even in the absence of an externally applied field, provided both the potential and the state-dependent diffusion constant are periodic with a relative phase difference. Later Landauer [10] considered this aspect of the problem again in the light of van Kampen’s work. Sinha and Moss [11] have verified Landauer’s conjecture by computer simulation. This has also been applied to thermal activation in a superconducting ring with a weak link where transitions produce temperature changes [12]. Indeed, a whole new field of research has emerged centering on the idea of the possibility of directed motion out of noisy states under diverse athermal driving conditions, generically subsumed under ‘thermal ratchets’ [13-18], and traceable to the original ‘blowtorch theorem’ of Landauer in the sense that the latter may be viewed as injection of noise [19].

Most of the investigations based on the blowtorch effect study the influence of space-dependent temperature on the steady-state relative occupations of the energy minima. To the best of authors’ knowledge, there has been no analytical attempt to study the kinetic aspect of the system, specifically, the calculation of the longest of relaxation time in a bistable potential in the presence blowtorch (hot zone). In this work, we address this problem and calculate the equilibration rate for a simple bistable potential with the localized heating positioned somewhere in the (unstable) intermediate region. The associated Smoluchowski equation describing the physical situation will be dealt with using the supersymmetric (SUSY) approach [20-22]. In doing so, we have adapted the supersymmetric potential approach normally applicable to the original Kramers barrier-crossing problem, to the case where the temperature is nonuniform along the reaction coordinate.

The rest of the paper is organized as follows. Section 2 contains a brief introduction to the SUSY method for extracting the longest relaxation rate (i.e., equilibration rate) from the Smoluchowski equation for the case where temperature is space-dependent. In section 3, applying the SUSY method to a model double-well potential with a hot zone, we obtain a matrix equation determining the equilibration rate. In section 4, we present an approximate
analytical expression obtained from the matrix equation. The latter is also solved numerically for the sake of comparison. As an independent check for these results, we have solved the Smoluchowski equation numerically and obtained the equilibration rate. The results we obtained from the above three ways for the equilibration rate as a function of different parameters characterizing the hot zone are, then, discussed. We devote the last section to summary and conclusions.

2 The methodology

The Smoluchowski equation describing the kinetics of a Brownian particle in an inhomogeneous medium is given by

\[
\frac{\partial P(x,t)}{\partial t} = \frac{\partial}{\partial x} \left[ \mu(x) \left( U'(x)P(x,t) + \frac{\partial}{\partial x} (T(x)P(x,t)) \right) \right]
\]  

(1)

where the mobility, \(\mu\), and temperature, \(T\), are in general space-dependent. (We take Boltzmann’s constant, \(k_B = 1\).) Here, \(P(x,t)\) is the probability density of finding the particle at position \(x\) at time \(t\) and \(U(x)\) describes the potential profile and the prime on \(U\) denotes the derivative with respect to \(x\).

Some remarks on the use of the Smoluchowski equation, Eq.(1), for the case of inhomogeneous medium are in order at this point as the latter has been a subject of some debate that still continues \[8, 11, 13, 23, 24\]. Landauer has argued \[10, 19\] for a generalization of the Smoluchowski equation where the second term on the RHS of Eq.(1) is to be replaced by \(P(x,t) \left( \frac{\partial T(x)}{\partial x} \right) + \alpha T(x) \left( \frac{\partial P(x,t)}{\partial x} \right)\). The parameter \(\alpha\) was shown to depend on the physical conditions to be imposed across the temperature discontinuity for no net current. The parameter \(\alpha = 0.5\) corresponds to a particle interacting with the thermal bath for which the particle velocity is taken to be proportional to \(\sqrt{T}\) or \(P(x) \propto \frac{1}{\sqrt{T(x)}}\). On the other hand, \(\alpha = 1\) corresponds to the case when particles equilibrate via collision (pressure equilibration), \(i.e.,\), \(P(x) \propto \frac{1}{T(x)}\). However, a direct derivation based on phase space Smoluchowski equation by van Kampen gave Eq.(1) corresponding to \(\alpha = 1\). This is also supported by the work of Jayannavar and Mahato \[25\] based on a microscopic treatment of the thermal bath as a set of harmonic oscillators. In our work, we will continue to use Eq.(1) as providing a physically valid description of the problem under consideration.

We consider the case where temperature is space-dependent but the medium is homogeneous so that the mobility, \(\mu\), is taken to be constant. Similar assumption of constant \(\mu\) has been taken by Sinha and Moss in their work \[11\]. Then, the corresponding Smoluchowski equation is

\[
\frac{\partial P(x,t)}{\partial t} = \mu \frac{\partial}{\partial x} \left[ U'(x)P(x,t) + \frac{\partial}{\partial x} (T(x)P(x,t)) \right]
\]

(2)
The stationary solution of Eq.\((2)\) is given by

\[
P_{ss}(x) = \frac{C}{T(x)} \exp \left[ - \int_{-\infty}^{x} \frac{U'(\tilde{x})}{T(\tilde{x})} d\tilde{x} \right],
\]

where \(C\) is the normalization constant. In this work, we choose a simple temperature profile whose value is constant both outside and inside the hot zone with \(T = T_0\) and \(T = T_0 + T_b\) respectively, where \(T_b\) is the excess temperature above the constant background value \(T_0\). (See Eq.\((10)\).) Using the following transformation

\[
\phi(x) = T(x) \exp \left[ - \int_{-\infty}^{x} \frac{U'(\tilde{x})}{2T(\tilde{x})} d\tilde{x} \right] e^{-\lambda t}
\]

we convert Eq.\((2)\) to a Euclidean Schrödinger equation

\[
H_+ \phi_+ = A^+ A \phi_+ = E \phi_+.
\]

Here, \(E_+ = \frac{\lambda}{\mu T_0}\) and the operators \(A\) and \(A^+\) are given by

\[
A = \frac{f \partial}{\partial x} + \frac{U'(x)}{2f T_0}, \quad A^+ = -\frac{f \partial}{\partial x} + \frac{U'(x)}{2f T_0}.
\]

In Eq.\((3)\), the parameter \(f\) reflects the excess temperature defined by \(f = \sqrt{1 + s}\), with \(s = \frac{T_b}{T_0}\). Thus, for the interval of \(x\) outside the hot zone, the corresponding operators have \(f = 1\). The Hamiltonian \(H_+\) corresponds to the motion of a particle in the potential

\[
V_+(x) = \left( \frac{U'(x)}{2T(x)} \right)^2 - \frac{U''(x)}{2T(x)}.
\]

For a high barrier, the longest relaxation rate is determined by the smallest nonzero eigen-value \(\lambda_1\) associated with the first excited state of Eq.\((3)\). On the other hand, this eigenstate is degenerate with the ground state \(\phi_0\) of the ‘supersymmetric partner potential’ \(V_-(x)\) given by

\[
V_-(x) = \left( \frac{U'(x)}{2T(x)} \right)^2 + \frac{U''(x)}{2T(x)},
\]

such that

\[
H_- \phi_0 = AA^+ \phi_0 = E \phi_0,
\]

where \(E_- = \frac{\lambda}{\mu T_0}\). Thus, the problem of finding the equilibration rate amounts to finding the ground state eigenvalue of this ‘partner’ potential. It is worth pointing out here that for the temperature profile we use, we exclude the two points where \(T(x)\) is discontinuous. However, following the line of attack used for obtaining the solution of the Schrödinger equation in the presence of a delta function potential, we devise a technique of relating the wave functions on either sides of these points (Appendix A).
Here we would like to mention that the SUSY method is a powerful analytical method used for simple model potentials such as the W-potentials. The applicability for calculating the Kramers’ escape rate in a W-potential for a uniform temperature case has been demonstrated by Schönhammer [22]. We found this method to be particularly useful while investigating the influence of barrier subdivision on the escape rate where we have demonstrated the existence of optimal number of subdivisions that maximizes the escape rate [26].

3 The model and its solution

We consider a simple bistable potential in the form of a symmetric W-potential which is piecewise linear having the same magnitude in slope. It is described by the barrier height $U_0$ and the distance $2L_0$ between the two potential minima located at $x = \pm L_0$ on either side of the origin (Fig. 1a). The localized hot zone of a certain width is taken to be positioned somewhere between the two potential minima. We assume a simple temperature profile of the following form for the heat bath:

$$T(x) = T_0 + T_b \left[ \Theta(x - d_b + \frac{w_b}{2}) - \Theta(x - d_b - \frac{w_b}{2}) \right]. \quad (10)$$

Here, $\Theta(x)$ is the Heaviside function, $T_0$ is the background (constant) temperature and $T_b$ is the excess temperature of the hot zone. The parameters $d_b$ and $w_b$ specify, respectively, the distance of the mid-point of the hot zone from the barrier top and the width of the hot zone (Fig. 1b).

The corresponding supersymmetric ‘partner’ potential $V_-(x)$ with the hot zone is given by

$$V_-(x) = \frac{2u_0}{L_0} \left[ \delta(x + L_0) - \delta(x) + \delta(x - L_0) \right] + \left( \frac{u_0,1}{L_0} \right)^2. \quad (11)$$

This relation holds good at all points except at the two points of temperature discontinuity. Here, $u_0 = \frac{t_0}{2T_0}$ and $u_1 = \frac{w_0}{1+w}$. It is clear that the potential $V_-(x)$ takes a constant value $\left( \frac{u_0}{L_0} \right)^2$ outside the hot zone and $\left( \frac{u_1}{L_0} \right)^2$ within. Two additional repulsive and one attractive delta function potentials are superposed at different locations as shown in Fig. 1c. Changing the variable $x$ to $y = \frac{x}{L_0}$ gives a new dimensionless Hamiltonian $h_- = L_0^2 H_-$ such that

$$h_- \phi_-^0(y) = e_b \phi_-^0(y) \quad (12)$$

whose potential is

$$V_-(y) = 2u_0 \left[ \delta(y + 1) - \delta(y) + \delta(y - 1) \right] + (u_{0,1})^2. \quad (13)$$

Here, $e_b$ is a dimensionless quantity equal to $L_0^2 E_-$ or equivalently $\frac{L_0^2 \lambda_1}{\mu T_0}$. In the scaled form, the position of the mid-point of the hot zone from the top of the barrier and the width of the hot zone are defined by $d = \frac{d_b}{L_0}$ and $w = \frac{w_b}{L_0}$, respectively (see Fig. 1b). Henceforth, we
use only the reduced variables. Transfer matrix method has been used to find the equation governing the eigenvalue $e_b$. Below, we outline the procedure leaving the details to the Appendix A.

The ground state wave function, $\phi_0^-$, is taken to have the form $A_n e^{-k(y-y_n)} + B_n e^{k(y-y_n)}$ located with respect to the positions $y = y_n$ of each of the delta function potentials and at points of discontinuity in the temperature profile. The amplitudes $A_n, B_n$ and $A'_n, B'_n$ on either sides of these special points are shown in Fig. 1c. For regions outside the hot zone, the wave vector $k$ is given by

$$k_0 = \sqrt{u_0^2 - e_b},$$

while for within the hot zone it is given by

$$k_1 = \sqrt{u_1^2 - \frac{e_b}{1+s}}.$$  

The amplitudes $A'_4$ and $B'_4$ that appear just on the left side of the positive delta function potential located at $y = -1$ are related to $A_0$ and $B_0$ that appear on the right side of the positive delta function potential located at $y = 1$ through a transfer matrix $M$ such that

$$\begin{pmatrix} A'_4 \\ B'_4 \end{pmatrix} = M \begin{pmatrix} A_0 \\ B_0 \end{pmatrix}.$$  

The matrix $M$ is the product of successive transfer matrices which are derived in the Appendix A. Since we are looking for a bound state solution, $A'_4 = B_0 = 0$. This implies that the 11-matrix element of $M$ must be zero, i.e.,

$$M_{11} = 0,$$

the solution of which gives the value of $e_b$ and, hence, the equilibration rate.

4 Results and discussion

The effect of the hot zone on the equilibration rate for the given potential is studied in terms of the three parameters characterizing the hot zone: (i) the relative degree of hotness of the hot zone with respect to the rest of the heat bath, $s = \frac{T_b}{T_0}$, (ii) the scaled width of the hot zone, $w = \frac{w_b}{L_0}$ and (iii) the scaled distance of the hot zone from the top of the potential barrier, $d = \frac{d_b}{L_0}$. Since the hot zone is in between the top of the barrier and the right minimum, the parameters $d$ and $w$ can only take values between 0 and 1. On the other hand, the strength $s$ can take positive values for hot zone and negative values (greater than $-1$) for cold zone. In addition, for each of these cases we have studied the influence of the barrier height $u_0 = \frac{U_0}{2T_0}$ on the equilibration rate.
The change in the equilibration rate due to the presence of the hot zone is better appreciated in terms of a quantity which we call *enhancement factor*, $f_b$, and defined by

$$f_b = \frac{e_b}{e_0}$$

(18)

where $e_0$ stands for $e_b$ when there is no hot zone ($s = 0$). $f_b$ is nothing but the factor by which the equilibration rate improves due to the presence of the hot zone.

An expression for the enhancement factor in terms of all the relevant parameters can be found from Eq.(17). By noting that, for a high barrier, $k_0$ and $k_1$ can be expanded about $u_0$ and $u_1$, respectively, we find the enhancement factor to be approximately given by

$$f_b = \exp(s\sigma) \cosh(s\sigma) \frac{1 + s \exp(s\sigma) \sinh(\sigma) \exp(-2u_0d)}{1 + s \exp(s\sigma) \sinh(\sigma) \exp(-2u_0d)}.$$  

(19)

where $\sigma \equiv \frac{wu_0}{1+s}$. Even though this equation gives very accurate values comparable to those obtained by numerically solving Eq.(17), the above equation can be further approximated into a more transparent form when the hot zone is located half way down the top ($d = 0.5$) and is given by

$$f_b = \frac{1}{2} \left[ 1 + \exp \left( 2u_0w \frac{s}{1+s} \right) \right].$$

(20)

Equation (20) shows that for a given barrier height $u_0$ and width $w$, $f_b$ increases as the strength of the hot zone, $s$, increases and saturates for large values. In addition, the enhancement factor $f_b$ has an exponential dependence on both the width $w$ of the hot zone and the barrier height $u_0$. It may be noted that the above expression has the correct limiting behaviour as a function of both $s \to 0$ and $w \to 0$. Equation (19) shows that the enhancement factor $f_b$ saturates as the blowtorch is moved away from the top of the potential barrier.

As an independent check of the analytical results (Eq.(19)), we have numerically solved Eq.(3) for a given temperature and potential parameters. Before numerically obtaining $f_b$, we have studied the evolution of the probability distribution towards the steady state. This was done by using an initial probability distribution sharply peaked around the bottom of the right well. A 3-dimensional plot of the time evolution of the probability distribution towards the steady state is shown in Fig. 2a. The numerically obtained asymptotic steady state distribution is shown in Fig. 2b. This clearly has higher population in the left well than the right which in the absence of the hot zone would be symmetric about the origin. Our numerical results show that this asymptotic distribution is practically identical with the steady state distribution $P_{ss}(x)$ given by Eq.(3).

One direct method of determining the long time decay rate of the probability distribution is to allow the system to evolve for long enough time towards the steady state. At late stages when the probability distribution is observed not to show any appreciable change, we can calculate the decay rate by plotting the total probability on the right well as a function of
time on \((ln \ t\) scale). However, it must be mentioned here that for calculating the equilibration rate, a more efficient way is to take the initial distribution to be a distribution which is marginally different from the stationary distribution (given by Eq. (3)). Even so, high values of \(u_0 \ (\sim 10)\) take long computer time for the system to reach the near stationary state required for calculating the equilibration rate. For this reason, for the numerical works based on Eq. (2) we have limited our calculation to \(u_0 = 4\). Although this value of \(u_0\) satisfies the high barrier condition, it is on the low side.

We now consider the influence of the hot zone on the equilibration rate. We shall refer to the results obtained from the approximate analytic expression (Eq. (19)) as analytical results, exact results obtained by numerically solving the root of the equation (Eq. (17)) as semi-analytical results and the results obtained by numerically solving Eq. (2) as numerical results. Figure 3 shows plots of the enhancement factor \(f_b\) versus strength of the blowtorch \(s\) for various values of the barrier height \(u_0\) placing the blowtorch (of width \(w = 0.1\)) midway from the top of the potential \((d = 0.5)\). (The set of curves \(a, b\) and \(c\) refer to three different values of the barrier height \(u_0 = 4, 10\) and 15 respectively.) We have shown the analytical results by a dashed line, the semi-analytical results by a continuous line and the numerical results by filled circles. (For higher values of \(u_0\), we have shown only the analytical results and semi-analytical results, since numerical results are time consuming.) As can be seen from Fig. 3, for higher values of the barrier height \(u_0\), analytical results are not distinguishable from the semi-analytical results over the entire range of \(s\). This clearly reflects the fact that large \(u_0\) approximation made in obtaining Eq. (19) holds good. Consider the dependence of \(f_b\) on the width of the hot zone \(w\). Figure 4 shows plots of \(f_b\) as a function of \(w\) for \(u_0 = 4, 10\) and 15 labelled by \((a), (b)\) and \(c\) respectively for \(s = 1\) and keeping the blowtorch half way down the barrier top, \(i.e., d = 0.5\). As before, for \(u_0 = 4\), where we have numerical results, there is excellent agreement between the numerical results, and analytical and semi-analytical results over the entire range of \(w\). For \(u_0 = 10\) and 15, semi-analytical results are indistinguishable from the analytical results. Lastly, we consider the dependence of the enhancement factor, \(f_b\), on the position of the hot zone from the barrier top, \(d\). Figure 5 shows plots of \(f_b\) versus \(d\) for \(u_0 = 4, 10\) and 15 denoted by \((a), (b)\) and \(c\) respectively (keeping the strength of the hot zone \(s = 1\) and its width \(w = 0.1\)). For relatively low barrier height, \(u_0 = 4\), we see that the analytical results agree well with the semi-analytical results and the numerical results. Unlike for small barrier height for which \(f_b\) saturates slowly, for large barrier heights \((b)\) and \(c\), \(f_b\) saturates quickly and stays nearly constant beyond \(d \sim 0.2\). Here again, the analytical results agree very well with the semi-analytical results. The above results reveal that the equilibration rate is higher when the hot zone is away from the barrier top.

The above dependence of enhancement factor \((f_b)\) for the equilibration rate on the position of the blowtorch \((d)\), shown in Fig.5, is intriguing. The enhancement factor is seen to saturate
quickly (to a value greater than unity) as the blowtorch moves away from the barrier top (i.e., as \( d \) increases beyond \( \frac{U_0}{U} \)), while it decreases towards unity as the blowtorch approaches the top of the potential barrier. (Of course, for sufficiently small \( d \), the hot zone begins to bracket the potential maximum because of finite width.) The above general feature may be physically understood in terms of an argument due to Landauer [27] based on the equilibration rate, 
\[
\frac{1}{\tau} = \frac{1}{\tau_L} + \frac{1}{\tau_R},
\]
for the occupation of the two wells, where \( \tau_L \) and \( \tau_R \) refer to the time for crossing the barrier from the left and from the right, respectively. Thus, for a blowtorch on the right side of the barrier, we expect not only \( \tau_R \) to increase as we approach the top of the barrier (as \( d \) decreases), but also \( \tau_L \) should increase as the particles crossing the barrier from the left well will be returned back by the blowtorch. This might qualitatively explain the result of \( d \) dependence of the enhancement factor, \( f_b \). However, this argument does not enable us to estimate the relative importance of the two effects, namely, the variation of \( \tau_L \) and \( \tau_R \) with \( d \). To clarify this point, we have carried out calculation of \( \tau \) for a highly asymmetric double-well potential in the limit of a very deep right well. We considered two cases — (i) when the hot zone is placed to the right of the barrier top and (ii) when it is to the left. This enabled us to isolate to a very good approximation the \( d \) dependence of \( \tau_L \) and \( \tau_R \) respectively from \( \tau(d) \). Our finding is that the decrease in the enhancement factor, \( f_b \), as \( d \) decreases is dominated by the increase of \( \tau_R \), although \( \tau_L \) also increases weakly. This is somewhat counterintuitive.

5 Summary and conclusions

In summary, we have been able to study the kinetic aspect of Landauer’s blowtorch theorem using the supersymmetric approach and using a simple model \( W \)-potential. The choice of the \( W \)-potential is particularly well adapted to the SUSY method. Our analysis shows that the rate of equilibration is substantially improved due to the presence of the hot region. The exact magnitude depends on its strength, its width, its location and also on the barrier height. We have also obtained an approximate analytical expression for the equilibration rate from transfer matrices derived using the SUSY method. These results agree well with the results obtained by numerical solution of the associated Smoluchowski equation.

We expect that the present analysis would be useful in understanding some problems when local heating is viewed in a more general context of local noise injection. Viewed from this angle, these results are clearly applicable even when fluctuations are athermal. One example where athermal fluctuations play an important role is the depinning of dislocation segments from obstacles resulting in movement of dislocations [28]. Another example where the present analysis may be useful is the study of kinetics of phase transformations. In this case, the free energy takes the role of the potential and the order parameter takes the role of the reaction coordinate. However, it is worth pointing out that in general, subjecting a range of order parameter values to excess heating is not easy since there is no correspondence
between the values taken by the order parameter and its location in space. In this context, martensite transformation offers a promising physical situation where we are actually dealing with the free energy in terms of strain order parameter. It would be interesting to realize the applicability of the present analysis to some experimental situations.

Authors would like to thank Prof. Rolf Landauer for very insightful comments. One of the authors (MB) would like to thank The International Program in Physical Sciences, Uppsala University, Uppsala, Sweden for financial support for this work. He would also like to thank Indian Institute of Science, particularly the Materials Research Centre Theory Group, for providing the necessary research facilities.
Appendix A

In this appendix we outline the method of evaluating the matrix $M$ that relates the amplitudes $A'_4$, $B'_4$ of $\phi^0_-$ found on the left side of the delta function potential at $y = -1$ to the amplitudes $A_0$, $B_0$ found on the right side of the delta function potential at $y = 1$. (See Fig. 1c.)

The region of the $W$ potential has four intervals of constant potential $V_-(x)$ marked by I, II, III and IV as shown in Fig. 1c. In these intervals, only simple phase changes in the wave function occur. In contrast, the wave function changes in a significant way across regions of temperature discontinuity and at points where delta functions are present. First, consider the phase changes which are simple to evaluate. The pairs of amplitudes $A_{n+1}$ and $B_{n+1}$ at the left end of these regions (I to IV) are related to those at the right end, $A'_n$ and $B'_n$, through the matrix equation

$$
\begin{pmatrix}
A_{n+1} \\
B_{n+1}
\end{pmatrix}
= P(a)
\begin{pmatrix}
A'_n \\
B'_n
\end{pmatrix}
$$

where

$$P(a) = \begin{pmatrix} e^{-ka} & 0 \\ 0 & e^{ka} \end{pmatrix}.$$  \hspace{1cm} (21)

Here $a$ stands for the width of the concerned interval and $k$ is either $k_0$ or $k_1$ depending on whether the interval is outside or within the hot zone.

Now, consider relating the amplitudes across the points of discontinuity in the temperature profile. The probability density $P(y, t)$ which is related to $\phi^0_-(y)$ through the transformation Eq.(4), is a continuous function of the position including the two points where temperature is discontinuous. Therefore, $\phi^0_-(y)$ on either side of these two points must be discontinuous in such a way that $P(y, t)$ remains continuous. In particular, at $y_1 = d + \frac{w}{T}$, using Eq.(3) and using the continuity condition $P(y_1^+, t) = P(y_1^-, t)$, we get

$$\phi^0_-(y_1^+) = \frac{\phi^0_-(y_1^-)}{1 + s}.$$  \hspace{1cm} (23)

Here $y_1^\pm = y_1 \pm \epsilon$ with $\epsilon \to 0$.

The second relation between the amplitudes comes from integrating the SE equation, across $y_1$ and exploiting the continuity of $P(y, t)$. This leads to the continuity of $\frac{\partial P}{\partial y}(TP)$. At $y = y_1$, this implies that

$$(\phi^0_-(y_1^+))^' = (\phi^0_-(y_1^-))^',$$  \hspace{1cm} (24)

where the primes denote the spatial derivative. Using Eqs. (23) and (24), the pairs of amplitudes $A_1$, $B_1$ and $A'_1$, $B'_1$ found on the two sides of the discontinuous temperature
profile located at \( y_1 \) are related through the equation

\[
\begin{pmatrix}
A_1' \\
B_1'
\end{pmatrix} = M_1 \begin{pmatrix}
A_1 \\
B_1
\end{pmatrix}
\]

where

\[
M_1 = \frac{1}{2k_1} \begin{pmatrix}
(1 + s)k_1 + k_0 & (1 + s)k_1 - k_0 \\
(1 + s)k_1 - k_0 & (1 + s)k_1 + k_0
\end{pmatrix}.
\]

In the same way, the two sets of amplitudes \( A_2, B_2 \) and \( A_2', B_2' \) found on the two sides of the discontinuous temperature profile located at \( y_2 = d - \frac{w}{2} \) are related through the matrix equation

\[
\begin{pmatrix}
A_2' \\
B_2'
\end{pmatrix} = M_2 \begin{pmatrix}
A_2 \\
B_2
\end{pmatrix}
\]

where

\[
M_2 = \frac{1}{2(1 + s)k_0} \begin{pmatrix}
k_0 + (1 + s)k_1 & k_0 - (1 + s)k_1 \\
k_0 - (1 + s)k_1 & k_0 + (1 + s)k_1
\end{pmatrix}.
\]

We are now left with relating the amplitudes on either sides of the three delta function potentials located at \( y = -1, 0 \) and \( 1 \). At all these three delta functions, \( \phi^0 \) is continuous since temperature is continuous. Thus, the pairs of amplitudes \( A_0, B_0 \) and \( A'_0, B'_0 \) on the right and the left sides of the delta function located at \( y = 1 \) are related through

\[
A'_0 + B'_0 = A_0 + B_0.
\]

Integrating the Euclidean Schrödinger equation across this positive delta function with the width of the integration tending to zero gives a second relation between these amplitudes:

\[
A'_0 - B'_0 = -\frac{2u_0}{k_0} (A_0 + B_0) + A_0 - B_0.
\]

These two relations gives a matrix equation relating the two sets of amplitudes:

\[
\begin{pmatrix}
A'_0 \\
B'_0
\end{pmatrix} = M_+ \begin{pmatrix}
A_0 \\
B_0
\end{pmatrix}.
\]

The same transfer matrix \( M_+ \) also relates the pairs of amplitudes \( A'_4, B'_4 \) to \( A_4, B_4 \) since features around \( y = 1 \) are identical to those around \( y = -1 \). When relating the pairs of amplitudes \( A_3, B_3 \) to \( A'_3, B'_3 \) corresponding to the two sides of the delta function located at \( y = 0 \), we note that the only difference is that the sign of the delta function is negative. Going through the same procedure as above we get the matrix equation:

\[
\begin{pmatrix}
A'_3 \\
B'_3
\end{pmatrix} = M_- \begin{pmatrix}
A_3 \\
B_3
\end{pmatrix}.
\]

The transfer matrices \( M_\pm \) are given by

\[
M_\pm = \frac{1}{k_0} \begin{pmatrix}
k_0 \mp u_0 & \mp u_0 \\
\pm u_0 & k_0 \pm u_0
\end{pmatrix}
\]

Using all the transfer matrices relating the successive sets of amplitudes, the matrix \( M \) is given by

\[
M = M_+ P(1) M_- P(d - \frac{w}{2}) M_2 P(w) M_1 P(1 - d - \frac{w}{2}) M_+.
\]
Figure Captions

Figure 1: (a) The $W$ potential, (b) Temperature profile $T(x)$, having the hot zone, (c) SUSY partner potential, $V_-(x)$.

Figure 2: (a) Time evolution of the probability distribution $P(x, t)$, towards the steady state for a given temperature. The parameter values are: $s = 1.0$, $u_0 = 4$, $w = 0.1$ and $d = 0.5$. (b): Very late stage probability distribution obtained by numerically integrating Eq. (2) taken as the steady state distribution. Note the dip in the probability value at the location of the hot zone shown by an arrow.

Figure 3: Plot of $f_b$ versus $s$, for $d = 0.5, w = 0.1$ for the values of (a) $u_0 = 4$, (b) $u_0 = 10$ and (c) $u_0 = 15$. Dashed lines correspond to the results from Eq. (19), solid lines to the semi-analytical method and filled circles to numerical solution.

Figure 4: Three plots of $f_b$ versus $w$, for $d = 0.5, s = 1$ for the values of (a) $u_0 = 4$, (b) $u_0 = 10$ and (c) $u_0 = 15$. Dashed lines correspond to the results from Eq. (19), solid lines correspond to the semi-analytical method and filled circles to numerical solution.

Figure 5: Plots of $f_b$ versus $d$ for $s = 1.0, w = 0.1$ for the values of (a) $u_0 = 4$, (b) $u_0 = 10$ and (c) $u_0 = 15$. Dashed lines correspond to the results from Eq. (19), solid lines correspond to semi-analytical results and filled circles to numerical solution.
