1. Introduction

One expects that at sufficiently high temperatures and densities the strongly interacting matter undergoes a transition to a new state, where quarks and gluons are no longer confined in hadrons, and which is therefore often referred to as a deconfined phase or Quark Gluon Plasma (QGP). The main goal of heavy ion experiments is to create such form of matter and study its properties. We would like to know at which temperature the transition takes place and what is the nature of the transition as well the properties of the deconfined phase, equation of state, static screening lengths, transport properties etc. Lattice QCD can provide first principle calculation of the transition temperature, equation of state and static screening lengths (see Ref. [1, 2]) for recent reviews. Calculation of transport coefficients remains an open challenge for lattice QCD (see discussion in Refs. [3, 4]).

One of the most interesting question for the lattice is the question about the nature of the finite temperature transition and the value of the temperature $T_c$ where it takes place. For very heavy quarks we have a 1st order deconfining transition. In the case of QCD with three degenerate flavors of quarks we expect a 1st order chiral transition for sufficiently small quark masses. In other cases there is no true phase transition but just a rapid crossover. Lattice simulations of 3 flavor QCD with improved staggered quarks (p4) using $N_r = 4$ lattices indicate that the transition is first order only for very small quark masses, corresponding to pseudo-scalar meson masses of about 60 MeV [10]. A recent study of the transition using effective models of QCD resulted in a similar estimate for the boundary in the quark mass plane, where the transition is 1st order [8]. This makes it unlikely that for the interesting case of one heavier strange quark and two light $u, d$ quarks, corresponding to 140 MeV pion, the transition is 1st order. However, calculations with unimproved staggered quarks suggest that the transition is 1st order for
pseudo-scalar meson mass of about 300 MeV [11]. Thus the effect of the improvement is significant and we may expect that the improvement of flavor symmetry, which is broken in the staggered formulation, is very important. But even when using improved staggered fermions it is necessary to do the calculations at several lattice spacings in order to establish the continuum limit. Recently, extensive calculations have been done to clarify the nature of the transition in the 2+1 flavor QCD for physical quark masses using $N_t = 4, 6, 8$ and 10 lattices. These calculations were done using the so-called *stout* improved staggered fermion formulations which improves the flavor symmetry of staggered fermions but not the rotational symmetry. The result of this study was that the transition is not a true phase transition but only a rapid crossover [12]. New calculations with stout action indicate that only for quark masses about ten times smaller than the physical quark mass the transition could be first order [13]. Even-though there is no true phase transition in QCD thermodynamic observables change rapidly in a small temperature interval and the value of the transition temperature plays an important role. The flavor and quark mass dependence of many thermodynamic quantities is largely determined by the flavor and quark mass dependence of $T_c$. For example, the pressure normalized by its ideal gas value for pure gauge theory, 2 flavor, 2+1 flavor and 3 flavor QCD shows almost universal behavior as function of $T/T_c$ [9].

The chiral condensate $\langle \bar{\psi}\psi \rangle$ and the expectation value of the Polyakov loop $\langle L \rangle$ are order parameters in the limit of vanishing and infinite quark masses respectively. However, also for finite values of the quark masses they show a rapid change in vicinity of the transition temperature. Therefore they can be used to locate the transition temperature. The fluctuations of the chiral condensate and Polyakov loop have a peak at the transition temperature. The location of this peak has been used to define the transition temperature in the calculations with p4 action on lattices with temporal extent $N_t = 4$ and 6 for several values of the quark mass [7]. The combined continuum and chiral extrapolation then gives the value $T_c = 192(7)(4)$ MeV. In this calculations the lattice spacing has been fixed by the Sommer parameter $r_0 = 0.469(7)$ fm [16]. The last error in the above value of $T_c$ corresponds to the estimated systematic error in the extrapolation. Recently the transition temperature has been determined using the so-called *stout* staggered action and $N_t = 4, 6, 8$ and 10 [19]. The deconfinement temperature has been found to be $176(3)(4)$ MeV [19]. The central value is considerably smaller than the one obtained with p4 action but taking into account the errors the deviation is not very significant. The authors of Ref. [19] use a different definition of the chiral susceptibility which resulted in the chiral transition temperature of $T_{chiral} = 151(3)(3)$ MeV. Using the chiral susceptibility defined above would result in a larger value of the transition temperature. Although the continuum extrapolation using only $N_t = 4$ and 6 is not completely reliable new calculations by *HotQCD Collaboration* using $N_t = 8$ lattices give quite similar results for the Polyakov loop, chiral condensate and strangeness susceptibility as earlier calculations with $N_t = 4$ and 6 lattices both for the p4 and asqtad action [20].

Lattice calculations of equation of state were started some twenty years ago. In the
case of QCD without dynamical quarks the problem has been solved, i.e. the equation of state has been calculated in the continuum limit [21]. At temperatures of about $4T_c$ the deviation from the ideal gas value is only about 15% suggesting that quark gluon plasma at this temperature is weakly interacting. Perturbative expansion of the pressure, however, showed very poor convergence at this temperature [22]. Only through the use of new re-summed perturbative techniques it was possible to get agreement with the lattice data [23, 24, 25]. To get a reliable calculation of the equation of state on the lattice, improved actions have to be used [26, 27]. Recently equation of state have been calculated using p4 and asqtad improved staggered fermion actions [28, 29]. In lattice calculation the basic thermodynamic quantity is the trace of the energy momentum tensor, often refered to as the interaction measure $\epsilon - 3p$. This is because it can be expressed in terms of expectation values of gauge action and quark condensates (see discussion in Ref. [29]). All other thermodynamic quantities, pressure, energy density and entropy density $s = (\epsilon + p)$ can be obtained from it using integration

$$\frac{p(T)}{T^4} - \frac{p(T_0)}{T_0^4} = \int_{T_0}^{T} dT' \frac{\epsilon(T') - 3p(T')}{T'^5}$$

The value of $T_0$ is chosen to be sufficiently small so that it corresponds to vanishing pressure to a fairly good approximation. In Fig. 1 I show the interaction measure form the new calculations with p4 action on $N_\tau = 4$ and 6 lattices [29]. At highest temperatures calculations with $N_\tau = 8$ lattices have also been performed. As expected because of use of the improved action the difference between the $N_\tau = 4$ and $N_\tau = 6$ results is small. In this figure I also show the entropy density which raises rapidly in the temperature region $180 - 200$ MeV. At high temperature it is only 10% below the ideal gas limit in agreement with expectations from improved perturbative calculations. The results from calculations with the asqtad action [28] are also shown. These calculations agree very well with the p4 results providing further evidence that the cutoff effects are small.
2. Spatial correlation functions

To get further insight into properties of the quark gluon plasma one can study different spatial correlation functions. One of the most prominent features of the quark gluon plasma is the presence of chromoelectric (Debye) screening. The easiest way to study chromoelectric screening is to calculate the singlet free energy of static quark anti-quark pair (for recent review on this see Ref. [30]), which is expressed in terms of correlation function of temporal Wilson lines

\[ \exp(-F_1(r,T)/T) = \text{Tr}(W(r)W^\dagger(0)). \]

\( L = \text{Tr}W \) is the Polyakov loop. This quantity is also useful to study quarkonia binding at high temperatures [31, 32, 33, 34, 35, 36]. In purely gluonic theory the free energy grows linearly with the separation between the heavy quark and anti-quark in the confined phase. In presence of dynamical quarks the free energy is saturated at some finite value at distances of about 1 fm due to string breaking [30, 37, 38]. Above the deconfinement temperature the singlet free energy is exponentially screened, at sufficiently large distances [38], i.e.

\[ F_1(r,T) = F_\infty(T) - \frac{4}{3} \frac{g^2(T)}{4\pi r} \exp(-m_D(T)r). \]

The inverse screening length or equivalently the Debye screening mass \( m_D \) is proportional to the temperature. In leading order of perturbation theory it is \( m_D = \sqrt{1+3N_f/g(T)T} \). Beyond leading order it is sensitive to the non-perturbative dynamics of the static chromomagnetic fields. The Debye screening mass has been calculated in pure gauge theory \( (N_f = 0) \) [38] and in 2 flavor QCD \( (N_f = 2) \) [39] as well as in 2+1 flavor QCD [40]. The temperature dependence of the lattice data have been fitted with the simple Ansatz motivated by the leading order result: \( m_D(T) = A\sqrt{1+N_f/3g(T)T} \). Here \( g(T) \) is the two loop running coupling constant. This simple form can fit the data quite well if \( A \simeq 1.4 - 1.6 \) [40]. Thus the temperature dependence as well as the flavor dependence of the Debye mass is given by perturbation theory. We also see that non-perturbative effects due to static magnetic fields significantly affect the electric screening, resulting in about 40% corrections. However, the non-perturbative correction is the same in full QCD and pure gauge theory.

3. Spectral functions

Information on hadron properties at finite temperature as well as transport coefficients are encoded in different spectral functions. In particular the fate of different quarkonium states in the quark gluon plasma can studied by calculating the corresponding quarkonium spectral functions. On the lattice we can calculate correlation function in Euclidean time. The later is related to the spectral function via integral relation

\[ G(\tau,T) = \int_0^\infty d\omega \sigma(\omega,T)K(\tau,\omega,T), \quad K(\tau,\omega,T) = \frac{\cosh(\omega(\tau - 1/2T))}{\sinh(\omega/2T)}. \]
Given the data on the Euclidean meson correlator $G(\tau, T)$ the meson spectral function can be calculated using the Maximum Entropy Method (MEM) \[41\]. For charmonium this was done by using correlators calculated on isotropic lattices \[42, 43\] as well as anisotropic lattices \[44, 45, 46\] in quenched approximation. It has been found that quarkonium correlation function in Euclidean time show only very small temperature dependence \[43, 46\]. In other channels, namely the vector, scalar and axial-vector channel stronger temperature dependence was found \[43, 46\], especially in the scalar and axial-vector channels. The spectral functions in the pseudo-scalar and vector channels reconstructed from MEM show peak structures which may be interpreted as a ground state peak \[44, 45, 43\]. Together with the weak temperature dependence of the correlation functions this was taken as strong indication that the 1S charmonia ($\eta_c$ and $J/\psi$) survive in the deconfined phase to temperatures as high as $1.6T_c$ \[44, 45, 43\]. A detailed study of the systematic effects show, however, that the reconstruction of the charmonium spectral function is not reliable at high temperatures \[46\], in particular the presence of peaks corresponding to bound states cannot be reliably established.

The only statement that can be is that the spectral function does not show significant changes withing errors of the calculations. Recently quarkonium spectral functions have been studied using potential models and lattice data for the free energy of static quark anti-quark pair \[36\]. These calculations show that all charmonia states are dissolved at temperatures smaller than $1.5T_c$, but the Euclidean correlators do not show significant changes and are in fairly good agreement with available lattice data both for charmonium \[43, 46\] and bottomonium \[46, 47\]. This is due to the fact that even in absence of bound states quarkonium spectral functions show significant enhancement in the threshold region \[36\]. Therefore previous statements about quarkonia survival at high temperatures have to be revisited. The large enhancement of the quarkonium correlators above deconfinement in the scalar and axial-vector channel can be understood in terms of the zero mode contribution \[36, 48\] and not due to the dissolution of the $1P$ states as previously thought. Similar, though smaller in magnitude, enhancement of quarkonium correlators due to zero mode is seen also in the vector channel \[46\]. Here it is related to heavy quark transport \[4, 35\]. In the vector channel the spectral function at very small frequency, i.e. the transport contribution is given by \[4\]

$$\sigma_{ii}^{\text{low}}(\omega) = \chi_q(T) v_{\text{therm}}^2 \frac{1}{\pi} \frac{\eta \omega}{\omega^2 + \eta^2},$$

with $\chi_q(T)$ being the quark number susceptibility for charm or bottom quarks and $v_{\text{therm}}$ is their thermal velocity. The width of the low energy transport contribution of the spectral functions is $\eta = T/(m_qD)$ with $m_q$ being the heavy quark mass and $D$ is the heavy quark diffusion constant \[4\]. Since $T/m_q$ is large $\eta$ is quite small and the transport peak in the spectral functions gives an almost constant contribution to the correlator. Deviation from the constant gives information about the value of $D$. However, existing lattice data are not precise enough to constrain its value. Existing lattice data can provide information about the thermal velocity of heavy quarks. On the lattice one can also calculate the temporal component of the vector correlator which is strictly
Figure 2. The thermal velocity of heavy quarks estimated using anisotropic lattice data [46] (filled symbols) and isotropic lattice data [43] (open symbols).

constant $G_{00}(\tau) = -\chi_q(T)T$ [4] because of charge conservation. Therefore calculating the transport contribution in the vector channel and dividing it by the temporal vector correlators gives an estimate of the thermal velocity of the heavy quarks. In Fig. 2 I show the estimated thermal velocity of the charm quarks using lattice data from isotropic and anisotropic lattices.

Note that for free quarks the thermal velocity squared is just $T/m_q$. As one can see from the figure the lattice data indicate significantly smaller thermal velocity even assuming a fairly large value for the effective quark mass $m_c = 1.7$GeV. Furthermore, we see a dramatic decrease of the thermal velocity at temperatures close to the transition temperature.

Although the above mentioned lattice studies were performed in quenched approximation we do not expect the picture to change when dynamical quarks are included in the calculations since recent calculations in 2-flavor QCD show very similar temperature dependence of charmonium correlators [49].

The spectral function for light mesons as well as the spectral function of the energy momentum tensor has been calculated on the lattice in quenched approximation [50, 51, 52, 53]. However, unlike in the quarkonia case the systematic errors in these calculations are not well understood.

4. Summary

Significant progress has been achieved in lattice calculations of thermodynamic quantities using improved staggered fermions. Pressure, energy density and entropy density can be reliably calculated at high temperatures when improved actions are used. Different lattice calculations show that for the physical quark masses the transition to the deconfined phase is not a true phase transition but a crossover. There is some controversy, however, concerning the location of the crossover. Lattice calculations provide detailed information about screening of static quarks which is important for the fate of heavy quarkonia in the quark gluon plasma. Some progress has been made
in calculating spectral functions on the lattice, however, much more work is needed in this case. One interesting result have been obtained for the thermal velocity of heavy quarks.
