**ABSTRACT:**

Childhood Acute Myeloid Leukemia (AML) is a clinically and genetically heterogeneous malignant disease. Despite improvements in outcome over the past decades, the current survival rate still is approximately 60-70%. Cytogenetic, recurrent genetic abnormalities and early response to induction treatment are the main factors predicting clinical outcome. While the majority of children carry recurrent chromosomal translocations, 20% of patients do not show any recognizable cytogenetic alteration and are defined to have cytogenetically normal acute myeloid leukemia (CN-AML). This subset of patients is characterized by a significant heterogeneity in clinical outcome, which is influenced by factors only recently started to be identified. In this respect, genome-wide analyses have been used with the aim of defining the full array of genetic lesions in CN-AML. Recently, through whole-transcriptome massively parallel sequencing of seven cases of pediatric CN-AML, we identified a novel recurrent CBFA2T3-GLIS2 fusion, predicting poorer outcome. However, since the expression of CBFA2T3-GLIS2 fusion in mice is not sufficient for leukemogenesis, we speculated that further unknown abnormalities could contribute to both cancer transformation and response to treatment. Thus, we analyzed, by whole-transcriptome sequencing, 4 CBFA2T3-GLIS2-positive patients, as well as 4 CN-AML patients. We identified a new fusion transcript in the CBFA2T3-GLIS2-positive patients, involving Desert Hedgehog (DHH), a member of Hedgehog family, and Ras Homologue Enrich in Brain Like 1 (RHEBL1), a gene coding for a small GTPase of the Ras family. Through the screening of a validation cohort of 55 additional pediatric AML patients, we globally detected DHH-RHEBL1 fusion in 8 out of 20 (40%) CBFA2T3-GLIS2-rearranged patients. Gene expression analysis performed on RNA-seq data revealed that DHH-RHEBL1-positive patients exhibited a specific signature. These 8 patients had an 8-year overall survival worse than that of the remaining 12 CBFA2T3-GLIS2-rearranged patients not harboring DHH-RHEBL1 fusion (25% vs 55%, respectively, \(P=0.1\)). Taken together, these findings are unprecedented and indicate that the DHH-RHEBL1 fusion transcript is a novel recurrent feature in the changing landscape of CBFA2T3-GLIS2-positive childhood AML. Moreover, it could be instrumental in the identification of a subgroup of CBFA2T3-GLIS2-positive patients with a very poor outcome.
INTRODUCTION

Childhood acute myeloid leukemia (AML) encompasses a heterogeneous group of malignancies, with great variability in terms of response to therapy. While the majority of patients harbor recurrent chromosomal translocations, almost 20% of childhood AML do not show any recognizable cytogenetic alteration and are defined as cytogenetically-normal (CN-AML) [1]. Recently, an increasing list of molecular markers with prognostic significance has been identified in adult CN-AML [2-8]. However, these alterations are barely detected in pediatric CN-AML [9-11] and there is a considerable proportion of children with CN-AML in whom no genetic abnormality can be unveiled.

In a recent study, we performed whole-transcriptome massively parallel sequencing of 7 cases of pediatric CN-AML; in 5 of them, we identified a novel recurrent fusion transcript involving CBF-A2T3 and GLIS2 genes. We then extended the analysis to a larger cohort (N=230) and this novel fusion was detected in 20 out of the 237 pediatric CN-AML cases analyzed (8.4%). The 5-year event-free survival of the 20 positive patients was significantly worse than that of the 217 pediatric CN-AML patients lacking the translocation (27.4% vs 59.6%; \( P=0.01 \)), demonstrating that CBF-A2T3-GLIS2 fusion transcript is a novel common feature of pediatric CN-AML predicting poorer outcome [12].

Despite this evidence in human AML, expression of CBF-A2T3-GLIS2 fusion is not sufficient to foster leukemia development in mice, this suggesting that the fusion protein per se may not promote leukemogenesis [13,14]. Starting from this observation, we reasoned that additional lesions can concur to leukemia development in children harboring CBF-A2T3-GLIS2 fusion transcript. Using whole-transcriptome sequencing, we identified a novel fusion transcript that is recurrent in CBF-A2T3-GLIS2-positive patients and is instrumental for the identification of a subset of CBF-A2T3-GLIS2-rearranged patients characterized by an even poorer outcome.

RESULTS

Identification of DHH-RHEBL1 fusion transcript in pediatric CBFA2T3-GLIS2-positive AML patients by whole-transcriptome sequencing

Blasts from 8 pediatric patients with AML were analyzed by means of whole-transcriptome massively parallel sequencing. Four of them had CN-AML (CN#21, CN#22, CN#23, CN#24), and 4 harbored CBFA2T3-GLIS2 fusion transcript (#1, #3, #13, #17). Among the latter, 2 had already been reported in our previous study [12]. Further analysis on RNA-seq data revealed the presence of a new recurrent fusion transcript in 2 out of 4 CBFA2T3-GLIS2-positive patients. This novel fusion transcript is the result of a read-through that combines at least part of one exon with each of two distinct (parent) genes that are adjacent on the same chromosome in the same orientation [15]. In particular, this transcript involves DHH, a member of the Hedgehog family [16], and RHEBL1, a gene coding for a small GTPase of the Ras family which regulates a wide variety of cellular functions, including cell growth, differentiation, and transformation [17]. Both genes are contiguously localized on the reverse strand of chromosome 12 (Figure 1A) and, although the mechanism that leads to generation of read-through fusion transcripts remains obscure [18], RT-PCR analysis and Sanger sequencing confirmed that all positive cases harbored the in-frame fusion between exon 2 of DHH and exon 2 of RHEBL1 (Figure 1B).

DHH-RHEBL1 fusion transcript is recurrent in pediatric CBFA2T3-GLIS2-positive AML

To determine the prevalence of DHH-RHEBL1 fusion in pediatric AML, we then examined a validation cohort of 55 children with AML. The validation cohort included CN-AML patients (N=24), CBFA2T3-GLIS2-positive patients (N=16), patients harboring known cytogenetic/genetic abnormalities (alteration of MLL, NPM1, FLT3, t(8;22)(p11;q13), t(9;11)(p22;q23), inv(16)(p13;q22)) (N=12) and normal CD34+ hematopoietic stem cells (N=3). The DHH-RHEBL1 fusion transcript was detected in 6 out of 16 patients carrying the CBFA2T3-GLIS2 fusion, while it was never found in the other patients with AML, irrespectively of the mutational status, as well as in normal CD34+ cells. Thus, considering also the patients of the sequencing cohort, the DHH-RHEBL1 fusion was globally present in 8 out of 20 (40%) of the CBFA2T3-GLIS2-positive patients, this demonstrating that this novel alteration is a common feature of this peculiar subset of childhood AML.

DHH-RHEBL1-positive patients exhibit a specific gene expression signature and an overexpression of both DHH and RHEBL1

To get insights into the molecular consequences of DHH-RHEBL1 expression, we performed a gene expression analysis on the RNA-seq data for the 8 patients carrying this fusion transcript. Firstly, we analyzed the expression level of the two genes involved in the fusion transcript and we found that the expression of both DHH and RHEBL1 is significantly enhanced in the DHH-RHEBL1-positive patients as compared with patients harboring only CBFA2T3-GLIS2 fusion (\( P=0.007 \) and \( P=0.009 \) respectively) and with the other CN-AML cases (\( P=0.0005 \) and \( P=0.043 \), respectively) (Figure
Additionally, *DHH-RHEBL1*-positive patients showed a distinctive gene expression signature both with respect to CBFA2T3-GLIS2-positive patients (518 differentially expressed genes; *P*<0.05), and CN-AML patients (596 differentially expressed genes; *P*<0.05). Interestingly, *DHH-RHEBL1*-positive patients showed

**Figure 1:** DHH-RHEBL1 is a novel fusion transcript recurrent in pediatric CBFA2T3-GLIS2 positive AML. (A) Schematic representation of the fusion between *DHH* and *RHEBL1* identified by means of whole-transcriptome sequencing. The figure shows the position of *DHH* and *RHEBL1* on chromosome 12 and the fusion transcript detected by RNA-seq. The identification of this novel fusion transcript was supported by an average of 11 span and 21 split reads. (B) Sanger sequencing performed in order to validate the detection of the *DHH-RHEBL1* fusion transcript. Electropherogram and predicted sequence of the fusion protein are shown. The black arrow indicates the fusion breakpoint.

**Figure 2:** Implications of DHH-RHEBL1 fusion transcript expression. (A) Expression levels of *DHH* and *RHEBL1* gene obtained from RNA-seq data in *DHH-RHEBL1* positive patients (N=2), in *CBFA2T3-GLIS2* positive patients (N=2) and in CN-AML patients (N=4). Abbreviations: CPM = count per million, Pos = positive (B) Probability of 8-year overall survival (OS) in *CBFA2T3-GLIS2*-positive children who did or did not harbor the *DHH-RHEBL1* fusion transcript (25%, SE=15 vs 55%, SE=15) (*P*=0.1).
Figure 3: Analysis of gene expression profile of DHH-RHEBL1-positive patients. Heatmap of the top 30 differentially expressed genes in DHH-RHEBL1-positive patients compared with the patients harboring the CBF A2T3-GLIS2 fusion only and CN-AML patients. (A) Gene expression signature of patients harboring both CBF A2T3-GLIS2 and DHH-RHEBL1 fusion transcript; (B) Gene expression signature of CBF A2T3-GLIS2-positive patients; (C) Gene expression signature of children with CN-AML not harboring any detectable fusion transcript. Abbreviation: Pos = positive.
higher expression of several genes known to be associated with leukemia occurrence and/or tumor progression, such as FLI3 [19], BEX1 [20], MUC4 [21] and AFAP1L2 [22] (Figure 3). Finally, we also evaluated whether the presence of DHH-RHEBL1 fusion transcript influences the outcome of CBFA2T3-GLIS2-positive patients. The 8-year overall survival of the 8 patients harboring the DHH-RHEBL1 fusion transcript was worse than that of the 12 CBFA2T3-GLIS2-rearranged patients not harboring the DHH-RHEBL1 fusion transcript (25% vs 55%). Likely due to the small number of patients, this difference failed to achieve statistical significance (P=0.1) (Figure 2B).

DISCUSSION

The last decades have witnessed the identification, through chromosomal analysis techniques or RT-PCR, of fusion genes influencing either proliferation/apoptosis or differentiation potential of AML cells [1-5]. Recently, different studies took advantage of next-generation sequencing approach to identify novel mutations or chromosomal aberrations that escape detection by conventional cytogenetic techniques and characterize pediatric AML, as well as other hematopoietic cancers [12,13,23-25]. Next-generation sequencing, as well as gene expression profiling, are also instrumental to refine the biological peculiarities affecting the risk of treatment failure and to detect crucial pathways potentially ‘druggable’ in both adult and childhood AML [2,26,27].

In this regards, we recently demonstrated that CBFA2T3-GLIS2 fusion transcript is recurrent in pediatric CN-AML and portends a poor outcome [12]. However, experimental evidence demonstrates that expression of this fusion product in mice is not sufficient to promote leukemogenesis [13,14]. This observation prompted us to investigate by whole-transcriptome sequencing a cohort of CN-AML and CBFA2T3-GLIS2-positive patients. We were able to identify a novel fusion transcript involving DHH and RHEBL1 genes in 2 out of 4 CBFA2T3-GLIS2-positive cases of our sequencing cohort. Extending the analysis to a validation cohort of 55 children, the DHH-RHEBL1 fusion was globally detected (including the 2 cases in the sequencing cohort) in 8 out of 20 (40%) of the CBFA2T3-GLIS2-positive patients, indicating that this novel fusion transcript is recurrent and peculiar to this specific group of pediatric CN-AML. Interestingly, both DHH and RHEBL1 genes have been implicated in a variety of human diseases, including cancer. On the one hand, DHH codes for a member of the Hedgehog (HH) signaling pathway, which, similar to other HH ligands, binds to its receptor Patched and leads to the signaling cascade of repressive interactions, culminating into effects on the transcription of target genes. The HH signaling, during embryogenesis, controls cell proliferation, differentiation and tissue morphogenesis [28]. However, it is also well known to have a role in tumors, and the role that HH signaling plays in the growth of tumors can be classified according to how the pathway is activated [29]. These mechanisms include loss-of-function mutations in inhibitory proteins, such as Patched (PTC1), gain-of-function mutations in positive regulators, such as Smoothened (SMO), and overexpression of the HH ligands (Sonic, Indian and Desert Hedgehog), leading to either autocrine or paracrine activation of the pathway and renewal/propagation of cancer stem cells [28]. Recently, with the identification of CBFA2T3-GLIS2 fusion transcript in pediatric CN-AML, different studies [13,14,23] demonstrated that the presence of this fusion transcript leads to an aberrant activation of the HH signaling due to the ectopic expression of the GLIS2 transcription factor. Notably, in the present work, we demonstrate that patients harboring the DHH-RHEBL1 fusion present an overexpression of DHH compared to both CBFA2T3-GLIS2-positive patients and CN-AML patients (Figure 2A). Considering that overexpression of the HH ligands leads to activation of the HH pathway [28], it is tempting to speculate that overexpression of DHH could contribute to the aberrant activation of the HH pathway. On the other hand, the RHEBL1 protein belongs to the Ras family of small GTPases and, similar to other Ras proteins, is a molecular switch that controls a wide variety of cellular functions including cell growth, differentiation and transformation [17]. Previous studies reported that RHEBL1 could function as an activator of NF-kB [17] and mTOR [30] signaling, both of which are frequently altered in many solid tumors, as well as in leukemias and lymphomas [27,31-36]. In view of RHEBL1 over-expression in patients harboring the DHH-RHEBL1 fusion transcript compared to those harboring only the CBFA2T3-GLIS2 fusion transcript and to CN-AML children, it will be interesting to investigate more thoroughly its possible role in leukemogenesis.

To define the implications, if any, of DHH-RHEBL1 fusion transcript expression, we performed an analysis of gene expression on RNA-seq data. Firstly, we demonstrated that patients harboring only the CBFA2T3-GLIS2 fusion transcript and patients harboring both CBFA2T3-GLIS2 and DHH-RHEBL1 fusion transcripts exhibited an overexpression of GLIS2 compared to CN-AML patients, this finding being consistent with recently published data [13,14,23]. In addition, and more importantly, gene expression profile revealed that DHH-RHEBL1-positive patients showed a specific gene expression signature, with 518 and 596 genes being significantly overexpressed when compared to patients harboring only the CBFA2T3-GLIS2 fusion transcript (P<0.05) and CN-AML patients (P<0.05), respectively. Interestingly, DHH-RHEBL1-positive patients exhibited an enhanced expression of FLI3, which has been reported to be constitutively activated and over-expressed in a proportion of both pediatric and adult AML [1,19]. Additionally, also BEX1, which is known to be expressed in AML with MLL rearrangements [20], was up-regulated.
Furthermore, other genes, such as MUC4 and AFAP1L2, associated with different human cancers [21,22], resulted overexpressed in DHH-RHEBL1-positive patients. Taken together, these findings indicate that DHH-RHEBL1-positive patients exhibit a distinct expression signature compared to both CN-AML patients and to CBFα2T3-GLIS2-positive patients (Figure 3), suggesting that the presence of DHH-RHEBL1 fusion transcript could be important in the definition of a new subgroup among the CBFα2T3-GLIS2-positive patients. To assess whether the presence of DHH-RHEBL1 fusion transcript affects patients’ outcome, we estimated the 8-year overall survival of the 8 patients harboring the DHH-RHEBL1 fusion transcript, finding that it was worse, although not statistically different, than that of the 12 CBFα2T3-GLIS2-rearranged patients not harboring DHH-RHEBL1 fusion (25% vs 55%).

While the discovery of gene fusion resulting from chromosomal aberrations, such as translocations, deletion/insertion, inversion, represents the primary objective of gene fusion analyses, whole-transcriptome sequencing aims at unraveling another category of gene fusion that are referred to as read-through fusion transcripts[15,18]. Several studies indicate that these groups of fusion transcripts are widely observed in virtually all samples analyzed, including samples from non-transformed different tissues [37]. Some of these RNA chimeras, however, appear to be restricted to individual tissue types, and a few of these have been observed to be highly expressed in cancers, this observation underpinning the potential functional relevance with respect to cellular differentiation and disease development [38-42]. To the best of our knowledge, DHH-RHEBL1 is the first read-through fusion transcript reported in a specific subset of pediatric leukemias and its recurrence in CBFα2T3-GLIS2-positive patients suggests it could be important for leukemogenesis. In summary, we discovered a novel DHH-RHEBL1 fusion transcript that is recurrent (40%) in CBFα2T3-GLIS2-positive patients only; it characterizes a subset of patients with an even more dismal outcome among the CBFα2T3-GLIS2-positive patients. The mechanism(s) through which this fusion transcript promotes leukemogenesis and the possibility of targeting it with pathway-specific compounds remain to be thoroughly investigated.

**METHODS**

**Patient samples**

After obtaining written informed consent, patient samples analyzed either in the parallel sequencing screening or in the validation cohort were collected from children with newly diagnosed de novo AML other than promyelocytic leukemia, enrolled in the Associazione Italiana Ematologia Oncologia Pediatrica (AIEOP) 2002/01 Protocol [43]. Morphological diagnosis and immunophenotypic analysis was centrally reviewed at the laboratory of Pediatric Hematology of the University Hospital in Padova. Chromosome analysis was performed on bone marrow (BM) aspirates using standard laboratory procedures. Karyotypes were reported according to the International System for Human Cytogenetic Nomenclature (ISCN 2005). For fluorescence in-situ hybridization (FISH), an MLL locus specific (LSI) dual color probe for 11q23 (Abbott-Vysis, Downers Grove, IL) was employed. All the 8 patients of the sequencing cohort were cytogenetically normal, as well as negative for known recurrent genetic abnormalities involving MLL, CBFβ, NPM1 and FLT3.

**Whole-Transcriptome Sequencing and RNA-seq bioinformatics analyses**

RNA library construction and whole-transcriptome sequencing has been described previously [12]. In brief, 250-1000 ng of total RNA were used for the synthesis of cDNA libraries with TruSeq RNA Sample Prep Kit v2 (Illumina, San Diego, CA), and sequenced by synthesis at 75bp in paired-end mode on HiScanSQ sequencer (Illumina). Reads were aligned with TopHat2/Bowtie2 [44] to the reference human genome hg19/GRCh37. Defuse [45] and Chimerascan [46] packages were used to detect chimeric transcripts from RNA-seq data. Whole-transcriptome massively parallel sequencing in the 8 children with CN-AML yielded an average of 78.4 million mapped reads/patient, thus reaching an average coverage of 34X.

**Gene expression analysis**

The mapped reads obtained with TopHat2/Bowtie2 pipeline were processed with SAMtools [47] in order to remove the potential optical or PCR duplicate (function "rmdup") and then the count of the mapped reads for each hg19 gene was performed by applying the Python package “htseq-count” (http://www-huber.embl.de/users/anders/HTSeq/doc/overview.html). Gene annotations were derived from Ensembl Release 70 (January 2013).

The differentially expressed genes were determined with edgeR, a R-bioconductor package suitable for analyzing RNA-seq data [48]. Three different comparisons were performed, corresponding to all the possible couples among the three groups of patients: 1) DHH-RHEBL1-positive and CBFα2T3-GLIS2-positive (N=2); 2) DHH-RHEBL1-negative and CBFα2T3-GLIS2-positive (N=2); 3) CN-AML (N=4).

For each comparison, the complete set of genes, with the corresponding mapped reads count, was firstly
reduced in order to consider in our analysis only the genes with count-per-million (CPM) > 3 in more than 2 samples. Then, adopting a statistical method based on the negative binomial distribution, the significance of the differences between the normalized reads count was determined for each gene. Differences with $P<0.05$ were considered to be statistically significant.

The Multi Experiment Viewer (MeV) tool (http://www.tm4.org/mev.html) was used to visualize the expression data.

**Screening for DHH-RHEBL1 fusion transcript in the validation cohort**

Total RNA was extracted from BM leukemia cells using TRIzol. DHH-RHEBL1 fusion transcript was detected through RT-PCR and sequenced with the BigDye terminator v3.1 Cycle Sequencing kit (PE Applied Biosystems, Foster City, CA) on an Applied Biosystems 310 analyzer. The RT-PCR was performed at 60°C with the Expand Long Template PCR system (Roche, Mannheim, Germany). Primers used to amplify the full **DHH-RHEBL1** fusion transcript (1359bp) were: forward 5’- AGTAGCAGGTCCTAGACCCCC -3’, reverse 5’- TACCCGTGAAGTCTTGAGGATCT -3’.
