Abstract

The LHCb Collaboration announced two pentaquark-like structures in the $J/\psi p$ invariant mass distribution. We show that the current information on the narrow structure at 4.45 GeV is compatible with kinematical effects of the rescattering from $\chi_{c1} p$ to $J/\psi p$. First, it is located exactly at the $\chi_{c1} p$ threshold. Second, the mass of the four-star well-established $\Lambda(1890)$ is such that a leading Landau singularity from a triangle diagram can coincidentally appear at the $\chi_{c1} p$ threshold, and third, there is a narrow structure at the $\chi_{c1} p$ threshold but not at the $\chi_{c0} p$ and $\chi_{c2} p$ thresholds. In order to check whether that structure corresponds to a real exotic resonance, one can measure the process $\Lambda_0^b \rightarrow K^- \chi_{c1} p$. If the $P_c(4450)$ structure exists in the $\chi_{c1} p$ invariant mass distribution as well, then the structure cannot be just a kinematical effect but is a real resonance, otherwise, one cannot conclude the $P_c(4450)$ to be another exotic hadron. In addition, it is also worthwhile to measure the decay $\Upsilon(1S) \rightarrow J/\psi p p$: a narrow structure at 4.45 GeV but not at the $\chi_{c0} p$ and $\chi_{c2} p$ thresholds would exclude the possibility of a pure kinematical effect.
The observation of many different hadrons half a century ago stimulated the proposal of the quark model as a classification scheme [1], and helped to establish quantum chromodynamics (QCD) as the fundamental theory of the strong interactions. Since then, hundreds of more hadrons were discovered. A renaissance of hadron spectroscopy studies started in 2003, and since then a central topic is the identification of the so called exotic hadrons. These are states beyond the naive quark model scheme, in which mesons and baryons are composed of a quark–antiquark pair and three quarks, respectively. Most of the new interesting structures were observed in the mass region of heavy quarkonium, and are called XYZ states (for a list of these particles and a review up to 2014, see Ref. [2]). In particular, the $X(3872)$ [3] extremely close to the $D_s^0\bar{D}_s^{*0}$ threshold is widely regarded as an exotic meson, and the charged structures with a hidden pair of heavy quark and heavy antiquark such as the $Z_c(4430)$ [4, 5], $Z_{c+}^{+}(3900)$ [6, 7], $Z_{c+}^{+}(4020)$ [8], and $Z_{c+}^{+}(10610, 10650)$ [9] would be explicitly exotic were they really resonances, i.e. poles of the $S$-matrix. Candidates for explicitly exotic hadrons were extended to the pentaquark sector by the new LHCb observations of two structures, denoted as $P_c$, in the $J/\psi p$ invariant mass distribution with masses (widths) $(4380 \pm 8 \pm 29)$ MeV ($(205 \pm 18 \pm 86)$ MeV) and $(4449.8 \pm 1.7 \pm 2.5)$ MeV ($(39 \pm 5 \pm 19)$ MeV), respectively [10]. They were suggested to be hadronic molecules composed of an anticharm meson and a charmed baryon [11, 12, 13] the existence of which were already predicted in Refs. [14, 15, 16, 17]. They were also discussed as a pentaquark doublet in Ref. [18].

Normally, such structures are observed as peaks in invariant mass distributions of certain final states, and fitted by using the Breit–Wigner parameterization to extract the masses and widths. However, such a procedure is problematic. On the one hand, many of these structures are very close to certain thresholds to which they couple strongly. In this case, a use of Breit–Wigner is questionable and one needs to account for the thresholds. This can be achieved using the Flatté parameterization [19] (a method in this spirit for near-threshold states with coupled channels and unitarity was recently proposed in Ref. [20]). On the other hand, not every peak should be attributed to the existence of a resonance. In particular, kinematical effects may also show up as peaks. Such kinematical effects correspond to singularities of the $S$-matrix as well, but they are not poles. In general, they are the so-called Landau singularities including branch points at thresholds and more complicated ones such as the triangle singularity, also called anomalous threshold (detailed discussions of these singularities can be found in the textbooks [21, 22]). The observability of the triangle singularity was extensively discussed in 1960s (see Refs. [23, 24, 25] and references therein), and recently was used to explain some structures including the $\eta(1405), a_1(1420)$ and $\phi(2170)$ [26, 27, 28, 29, 30, 31]. In fact, there were suggestions that some of the $Z_c$ and $Z_b$ states were threshold effects [32, 33, 34, 35, 36] and the threshold effects might be enhanced by triangle singularities [37]. For a general discussion of $S$-wave threshold effects, see also Ref. [38]. Therefore, in order to establish a structure as a resonance, one has to discriminate it from such kinematical effects. Indeed, this is possible. As discussed in Ref. [39], a resonance can be distinguished from threshold kinematical effects only in the elastic channel which is the channel with that threshold. The purpose of this paper is to discuss the possible kinematical effects for the narrower structure at 4.45 GeV in the LHCb observations and suggest measurements to check whether it is a real exotic resonance or not.

We first notice that the $P_c(4450)$ structure is exactly located at the threshold of a pair of $\chi_{c1}$ and proton, $(4448.93 \pm 0.07)$ MeV, and

$$MP_c(4450) - M_{\chi_{c1}} - M_p = (0.9 \pm 3.1) \text{ MeV}.$$  \hspace{1cm} (1)

If the angular momentum between the $\chi_{c1}$ and proton is a $P$-wave, then the two-body system can have quantum numbers $J^P = (1/2, 3/2, 5/2)^-$, compatible with the favored possibilities $5/2^+, 5/2^-$ and $3/2^-$ [10]. The $\chi_{c1}p$ can rescatter into the observed $J/\psi p$ by exchanging soft gluons. Two possible diagrams for such a mechanism are shown in Fig. 1, where (a) is a two-point loop with a prompt three-body production $\Lambda_b^0 \rightarrow K^- \chi_{c1} p$ followed by the rescattering process $\chi_{c1} p \rightarrow J/\psi p$, and in (b) the $K^- p$ pair is produced from an intermediate $\Lambda^*$ state and the proton rescatters with the $\chi_{c1}$ into the $J/\psi p$. We will discuss them subsequently.

It is worthwhile to notice that the $\chi_{c1}$ can be produced in the weak decays of the $\Lambda_b$ with a similar magnitude as that for the $J/\psi$. In the bottom quark decays, the charm quark is produced
Thus, the amplitude for Fig. 1 (a) is proportional to the nonrelativistic two-point loop integral

\[ \mathcal{O}_1 = [\bar{c}^\alpha \gamma^\mu (1 - \gamma_5) c^\alpha] [\bar{s}^\beta \gamma_\mu (1 - \gamma_5) b^\beta], \quad \mathcal{O}_2 = [\bar{c}^\alpha \gamma^\mu (1 - \gamma_5) c^\alpha] [\bar{s}^\beta \gamma_\mu (1 - \gamma_5) b^\beta], \]

(2)

where one-loop QCD corrections have been taken into account to form \( \mathcal{O}_1 \). Here, \( \alpha, \beta \) are color indices, and they should be set to be the same in \( \mathcal{O}_2 \) in order to form a color-singlet charmonium state. The quark fields, \( [\bar{c} \gamma^\mu (1 - \gamma_5) c] \), will directly generate the charmonium state. A charmonium with \( J^{PC} = 1^{--} \) like the \( J/\psi \) is produced by the vector current, while the axial-vector current tends to produce the \( \chi_{c1} \) with \( J^{PC} = 1^{++} \) and the \( \eta_c \) state with \( J^{PC} = 0^{++} \). Since the vector and axial-vector currents have the same strength in the weak operators, one would expect the production rates for the \( J/\psi \) and \( \chi_{c1} \) are of the same order in \( b \) quark decays. Corrections to this expectation come from higher-order QCD contributions but are sub-leading [40]. In fact, such an expectation is supported by the \( B \) meson decay data [2]:

\[ \mathcal{B}(B^+ \rightarrow J/\psi K^+) = (10.27 \pm 0.31) \times 10^{-4}, \quad \mathcal{B}(B^+ \rightarrow \chi_{c1} K^+) = (4.79 \pm 0.23) \times 10^{-4}. \] (3)

Having made these general observations, we return to the discussion of the \( \Lambda_b^0 \) decays measured by LHCb. We will first focus on the two-point loop diagram whose singularity is a branch point at the \( \chi_{c1} p \) threshold on the real axis of the complex \( s \) plane, where and in the following \( \sqrt{s} \) denotes the invariant mass of the \( J/\psi p \) or \( \chi_{c1} p \) system. It manifests itself as a cusp at the threshold if the \( \chi_{c1} p \) is in an \( S \)-wave. For higher partial waves, the threshold behavior of the amplitude is more smooth and a cusp becomes evident in derivatives of the amplitude with respect to \( s \). Since we are only interested in the near-threshold region, both of the \( \chi_{c1} \) and the proton are nonrelativistic. Thus, the amplitude for Fig. 1 (a) is proportional to the nonrelativistic two-point loop integral

\[ G_{\Lambda}(E) = \int \frac{d^3q}{(2\pi)^3} \frac{q^2 f_{\Lambda}(q^2)}{E - m_1 - m_2 - q^2/(2\mu)}, \]

(4)

where \( m_{1,2} \) denote the masses of the intermediate states in the loop, \( \mu \) is the reduced mass and \( E \) is the total energy. Here, we consider the case for the \( P \)-wave \( \chi_{c1} p \) which has quantum numbers compatible with the possibilities of the \( P_s(4450) \) reported by the LHCb Collaboration, though one should be conservative to take these determinations for granted as none of the singularities discussed here was taken into account in the LHCb amplitude analysis. If we take a Gaussian form factor, \( f_{\Lambda}(q^2) = \exp(-2q^2/\Lambda^2) \), to regularize the loop integral, the analytic expression for the loop integral is then given by

\[ G_{\Lambda}(E) = -\frac{\mu \Lambda}{(2\pi)^{3/2}} \left( k^2 + \frac{\Lambda^2}{4} \right) e^{-2k^2/\Lambda^2} \left[ \text{erfi} \left( \frac{\sqrt{2}k}{\Lambda} \right) - i \right]. \] (5)

with \( k = \sqrt{2\mu(E - m_1 - m_2 + i\epsilon)} \), and the imaginary error function \( \text{erfi}(z) = (2/\sqrt{\pi}) \int_0^z e^{t^2} dt \). A better regularization method should be applied in the future, but for our present study such an approach is fine.
Using an amplitude with the loop function given in Eq. (5), one can get a peak around the $\chi_{c1}p$ threshold. In order to have a more quantitative description of the effect of Fig. 1 (a), we fit to the Argand plot for the $P_c(4450)$ amplitude depicted in Fig. 9 (a) in Ref. [10] with an amplitude

$$A_{(a)} = N \left[ b + G_\Lambda(E) \right],$$

(6)

where $b$ is a constant background term which may originate from a direct production of the $K^- J/\psi p$, and $N$ is an overall normalization. We fit to both the real and imaginary parts of the $P_c(4450)$ amplitude by minimizing the sum of the chi-squared values for both the real and imaginary parts. The best fit with a real background term has $\chi^2$/d.o.f. = 1.75 and is given by $N = 3144$, $b = -2.9 \times 10^{-4}$ GeV$^4$ and $\Lambda = 0.16$ GeV. With a real background term, the amplitude in Eq. (6) can only be complex when the energy is larger than the $\chi_{c1}p$ threshold, as is evident in Fig. 2. The background is in general complex as a result of the fact that the $K, J/\psi$ and $p$ can go on shell and many $\Lambda$ resonances can contribute to the $Kp$ state. One sees from the figure that the counterclockwise feature of the LHCb amplitude is reproduced, and the overall agreement is good. The absolute value of the amplitude in Eq. (6) with these determined parameters has a narrow peak around the $\chi_{c1}p$ threshold as shown in Fig. 3 (a). We have checked that using a different form factor $\Lambda^4/(q^2 + \Lambda^2)^2$ gives a similar result. In both cases, the peak is asymmetric unlike the Breit–Wigner form.

There can be further enhancement around the $\chi_{c1}p$ threshold due to the presence of nearby triangle singularities, also called leading Landau singularities of a triangle diagram, from Fig. 1 (b). The leading Landau singularities for a triangle diagram are solutions of the Landau equation [41]

$$1 + 2 y_{12} y_{23} y_{13} = y_{12}^2 + y_{23}^2 + y_{13}^2,$$

(7)

where $y_{ij} = (m_i^2 + m_j^2 - p_{ij}^2)/(2 m_i m_j)$ with $m_i (i = 1, 2, 3)$ masses of the intermediate particles, and $p_{ij} = p_i + p_j$ being the four momentum of the $ij$ pair. To be specific, we let $m_1, m_2$ and $m_3$ correspond to the masses of the $\Lambda^*, J/\psi$ and proton, respectively. Then, $p_{12}^2 = M_{\Lambda^*}^2$, $p_{13}^2 = M_{J/\psi}^2$, and $p_{23}^2 = s$ is the invariant mass squared of the $J/\psi p$ pair. It is easy to solve this equation...
for any given variable. We solve it as an equation of $s$, which has two solutions. For an easy visualization, we plot in the left panel of Fig. 4 the motion of the solutions in the complex $\sqrt{s}$ plane. As discussed in 1960s, see e.g. Ref. [23], only one of the singularities can have an impact on the amplitude in the physical region defined on the upper edge of the real axis on the first Riemann sheet of the complex $s$-plane, and it is effective only in a limited region of one of these variables. Here we want to investigate in which values the $\Lambda^*$ mass can take so that there can be an evident singularity effect in the $J/\psi p$ invariant mass, $\sqrt{s}$. According to the Coleman–Norton theorem [42], the singularity is in the physical region only when the process can happen classically, which means that all the intermediate states are on shell, and the proton emitted from the decay of the $\Lambda^*$ moves along the same direction as the $\chi_{c1}$ and can catch up with it to rescatter. Let us start from a very large mass for the $\Lambda^*$ so that it cannot go on shell in Fig. 1 (b). Decreasing this mass, when it has a value $m_{1,\text{high}} = \sqrt{p_{12}^2 - m_2}$, it can go on shell. At this point, the $\chi_{c1}$ is at rest in the rest frame of the decaying particle $\Lambda_b$, and the proton emitted from the decay $\Lambda^* \to K^- p$ can definitely rescatter with the $\chi_{c1}$ classically. This is the point shown as a filled triangle with $M_{\Lambda^*} = 2.11$ GeV, labelled as A, on the solid curves in Fig. 4. If we decrease $m_1$ further, the $\chi_{c1}$ will speed up and the proton will slow down. Thus, the lower bound of $m_1$ for the rescattering process that happens classically is given by the case when the $\chi_{c1}$ and the proton are at a relative rest, i.e. when the $\chi_{c1} p$ invariant mass is equal to their threshold. Thus, at this point the triangle singularity coincide with the normal threshold, and one gets

$$m_{1,\text{low}} = \sqrt{p_{13}^2 m_3 + p_{13}^2 m_2 - m_2 m_3}.$$  

If $m_1$ is smaller than $m_{1,\text{low}}$, the proton would not be able to catch up with the $\chi_{c1}$ and the triangle diagram can only be a quantum process. For the case of Fig. 1 (b), $m_{1,\text{low}}$ is given by $M_{\Lambda^*} = 1.89$ GeV, labelled as B and also shown as a filled triangle in Fig. 1. In the left panel of Fig. 4, in order to move the singularity trajectories away from the real axis, we give a 10 MeV width to the $\Lambda^*$. For a vanishing width, the solid and dashed trajectories would pinch the real axis at $m_1 = m_{1,\text{high}}$. We can now know on which Riemann sheet of the complex $s$-plane the singularities are located. Since only when $m_1$ is between $m_{1,\text{low}}$ and $m_{1,\text{high}}$ (the part between the two filled triangles in the figure), the process can happen classically and the singularity can be on the physical boundary (if the $\Lambda^*$ width vanishes), we conclude that the singularity shown

Figure 3: Absolute values of amplitudes in arbitrary units: (a) is for the amplitude in Eq. (6) fitted to the Argand plot; (b) is the for the triangle loop integral with the $\chi_{c1} p$ vertex in a $P$-wave. In (b), we assume the $\Lambda(1890)$ with a mass of 1.89 GeV is exchanged in the triangle diagram. The solid, dashed and dotted lines correspond to a width of the $\Lambda(1890)$ of 10, 60 and 100 MeV, in order.
Figure 4: Left: Motion of the two triangle singularities in the complex plane of $\sqrt{s} = M_{\chi_c p} = M_{J/\psi p}$ with respect to changing the mass of the exchanged $\Lambda^*$ baryon (several values are labeled in the plot in units of GeV). In order to distinguish the trajectories from the real axis, we put a small imaginary part, $-5$ MeV corresponding to a width of 10 MeV, to $M_{\Lambda^*}$. Only the part between the two filled triangles, labelled as A and B, has a large impact on the physical amplitude. The thick solid straight line represents the unitary cut starting from the $\chi_c p$ threshold. Right: The corresponding Dalitz plot which shows the region between A and B.

as the solid curve is always on the second Riemann sheet. On the contrary, the singularity whose trajectory is shown as the dashed curve in the left panel of Fig. 4 is on the second Riemann sheet when it is above the real axis, and it moves into the lower half plane of the first Riemann sheet otherwise. Thus, it is always far away from the physical boundary, and does not have any visible impact on the physical amplitude. For an easy visualization of the kinematical region between A and B, we show the corresponding Dalitz plot in the right panel of Fig. 4.

An intriguing observation for the case of interest is that within the range between 1.89 GeV and 2.11 GeV, there is a four-star baryon $\Lambda(1890)$ with $3/2^+$. Taking $M_{\Lambda^*} = 1.89$ GeV, the triangle singularity is just at the $\chi_c p$ threshold which can provide a further threshold enhancement.\(^1\) Giving a finite width to the $\Lambda(1890)$, the singularity moves away from the real axis into the lower half plane of the second Riemann sheet (it is located at $(4.47 - i 0.2)$ MeV for $M_{\Lambda^*} = (1.89 - i 0.03)$ GeV), and the enhancement is reduced. The $\Lambda(1890)$ has a relatively small width (60 to 100 MeV [2]) so that there can still be an important enhancement. In Fig. 3 (b), we show the absolute value of the triangle loop integral with the $\chi_c p$ in a $P$-wave for three different widths (for a discussion of the triangle singularities in nonrelativistic triangle loop integral, see Ref. [43]). There is clearly an enhancement nearby 4.45 GeV even when the width is taken to be 100 MeV.

In the above, we have shown that kinematical effects can result in a narrow structure around the $\chi_c p$ threshold in the $J/\psi p$ invariant mass of the $\Lambda_b^0 \to K^- J/\psi p$ decay. Consequently, a natural question is whether such an effect happens at other thresholds, in particular those related to the $\chi_c p$ through heavy quark spin symmetry (HQSS). As a result of the HQSS, the operator for annihilating a $\chi_c$ and creating a $J/\psi$ is contained in

$$\frac{1}{2} \langle J^\dagger \chi \rangle = -\psi \chi_c^\dagger + \frac{1}{\sqrt{2}} \epsilon^{ijk} \psi \chi_c^\dagger + \frac{1}{\sqrt{3}} \delta^{ij} \psi \chi_c^\dagger + \eta_c h_c^i,$$

where the fields $J = \bar{\psi} \cdot \bar{\sigma} + \eta_c$ and $\bar{\chi} = \sigma^2 \left( -\xi^{ij} \chi_c^\dagger + \frac{1}{\sqrt{2}} \epsilon^{ijk} \chi_c^\dagger + \frac{1}{\sqrt{3}} \delta^{ij} \chi_c^\dagger \right) + h_c^i$ [44, 45] annihilate\(^1\) The mechanism of enhanced threshold effect due to the triangle singularity was recently discussed for the case of $Z_c$ and $Z_b$ states [37].
the $S$-wave and $P$-wave charmonium states, respectively. This means that the rescattering inter-
action strength for $\chi_{c2}p \to J/\psi p$ or $\chi_{c0}p \to J/\psi p$ is of similar size as that for the $\chi_{c1}p \to J/\psi p$.
One might naively expect enhancements at both the $\chi_{c2}p$ and $\chi_{c0}p$ thresholds in the $J/\psi p$ in-
variant mass as well. However, this is not the case. As we have shown in Eq. (2), at leading order
in $\alpha_s$, the charmonium is produced by the $[\bar{c}\gamma^\mu(1 - \gamma_5)c]$ current. This current has no projection
onto the $\chi_{c0}$ or $\chi_{c2}$. The production of the $\chi_{c0,2}$ in the $b$ decays can come only from higher-order
QCD corrections which are suppressed. Indeed, there is no enhancement at the $\chi_{c2}p$ and $\chi_{c0}p$
thresholds in $\Lambda_b$ decays, which is consistent with our expectation.

The above analysis is applicable to any $b$ quark decay in which the $\chi_{c0,2}$ is directly generated
by the weak interaction. But it would be different if the initial decay heavy particle contains a
charm or anticharm quark in addition to the bottom quark. Processes of this type include the
decays of the $B_c$ meson and the doubly-heavy baryon $\Xi_{bc}$. An explicit calculation of $B_c$
decays [46] indicates that the $\chi_{c0,2}$ can have similar production rates with the $\chi_{c1}$. Considering the large
amount of data on the $B_c$ to be accumulated by the LHCb collaboration [47], it appears very
promising to investigate the $\chi_{c0}$ and $\chi_{c2}$ thresholds in the future. In addition, one can study the threshold effects in the prompt production of the $J/\psi p$ at the LHC, or in the $\Upsilon(1S)$
decays into the $\chi_{cJ}pp$ and $J/\psi pp$.

In conclusion, what we have shown here is that the present information on the narrow structure
around 4.45 GeV observed by the LHCb Collaboration is compatible with kinematical effects
around the $\chi_{c1}p$ threshold: First, it is located exactly at the $\chi_{c1}p$ threshold. Second, the mass of the
four-star well-established $\Lambda(1890)$ coincidentally makes the triangle singularity on the physical
boundary located at the $\chi_{c1}p$ threshold, despite a small shift into the complex plane due to the
finite width of the $\Lambda(1890)$, and third, the $\chi_{c1}$, instead of the $\chi_{c0}$ or $\chi_{c2}$, can be easily produced
in the weak decays of the $\Lambda_b$ by the $V - A$ current so that there can be an evident effect at the
$\chi_{c1}p$, but not the $\chi_{c0}p$ or $\chi_{c2}p$, threshold.

Therefore, the most important question regarding the structure around 4.45 GeV is whether it
is just a kinematical effect or a real resonance. As discussed in Ref. [39], kinematical singularities,
including both the normal threshold and the triangle singularity, cannot produce a narrow near-
threshold peak in the elastic channel, which is the $\chi_{c1}p$ in this case. The reason is the interaction
strength in the elastic channel controls the threshold behavior, and there can be a narrow near-
threshold peak only when the interaction in the elastic channel is strong enough to produce a
pole in the $S$-matrix which corresponds to a real resonance. On the contrary, one cannot simply
determine the interaction strength for the inelastic channel ($\chi_{c1}p \to J/\psi p$ in our case) because it
can always interfere with a direct production of the final state. Thus, the question can be answered
by analyzing the process $\Lambda_b^0 \to K^-\chi_{c1}p$: if there is a narrow structure just above threshold in the
$\chi_{c1}p$ invariant mass distribution, then the structure cannot be just a kinematical effect and calls
for the existence of a real pentaquark-like exotic resonance, otherwise, one cannot conclude the
$P_c(4450)$ to be another exotic hadron.
