(Dated: May 5, 2014)

The weakly interacting massive particle (WIMP) often serves as a candidate for the cold dark matter, however when produced non-thermally it could behave like warm dark matter. In this paper we study the properties of the $\gamma$-ray emission from annihilation of WIMP dark matter in the halo of our own Milky-Way Galaxy with high resolution $N$-body simulations of a Milky-Way like dark matter halo, assuming different nature of WIMPs. Due to the large free-streaming length in the scenario of warm WIMPs, the substructure contend of the dark matter halo is significantly different from that of the cold WIMP counterpart, resulting in distinct predictions of the $\gamma$-ray signals from the dark matter annihilation. We illustrate these by comparing the predicted $\gamma$-ray signals from the warm WIMP annihilation to that of cold WIMPs. Pronounced differences from the subhalo skymap and statistical properties between two WIMP models are demonstrated. Due to the potentially enhanced cross section of the non-thermal production mechanism in warm WIMP scenario, the Galactic center might be prior for the indirect detection of warm WIMPs to dwarf galaxies, which might be different from the cold dark matter scenario. As a specific example we consider the non-thermally produced neutralino of supersymmetric model and discuss the detectability of warm WIMPs with Fermi $\gamma$-ray telescope.

I. INTRODUCTION

The so-called dark matter (DM), discovered \textasciitilde 80 years ago in the astronomical observations, is still one of the biggest mysteries in the fields of physics, astronomy and cosmology. To understand the nature of DM particles is a big challenge of the community. There are several ways being proposed to detect the WIMP DM particles (see e.g., \cite{1}), among which the indirect search through the cosmic ray (CR) particles is the most active one in recent years due to the operation of several new generation satellites, such as PAMELA, Fermi and AMS02. In many kinds of CR particles, the anti-particles, $\gamma$-rays and neutrinos are good probes to search for DM signals. Especially, $\gamma$-rays are widely discussed, due to the simple propagation and the high sensitivity detections from both spatial and ground-based telescopes. The constraints on the DM parameters become stronger and stronger in recent years thanks to the Fermi $\gamma$-ray observations \cite{2-6}.

One of the key problems in the study of the $\gamma$-ray emission from the WIMP DM annihilation is the density distribution of DM. It is observationally very difficult to determine the density distribution of DM, especially at small scales. Currently the postulated best knowledge about the DM density distribution comes from the numerical N-body simulations (e.g., \cite{7-8}).

The initial matter power spectrum which describes cosmic density perturbation depends on the particle nature of DM. For the cold DM (CDM), the particle velocity when decoupling is negligible and the corresponding free-streaming length is very short. The small free-streaming length enables structures down to very small scales to form.

The CDM scenario has been shown to be in good agreement with the observations of the cosmological large scale structures. However, it has been a long time problem of the CDM scenario that the expected structures are inconsistent with observations at sub-galactic scale (e.g., \cite{10-14}). One possible solution of this problem is the warm DM (WDM) scenario \cite{15-17}, or a recent review \cite{18}). In general, with a thermal distribution, the particle mass of the WDM should be as light as \textasciitilde keV. After decoupling the velocity of WDM can be fast enough to introduce a large free-streaming scale below which the structures are smoothed out. Thus the formation of small scale structures in the WDM scenario can be suppressed.

If the DM is finally proven to be warm, the impact on the detection of DM particles is fatal, because most of these experiments aim to search for the weakly interacting massive particles (WIMPs) which are traditionally cold. For the canonical WIMPs, when produced thermally in the early Universe, the velocity is non-relativistic after decoupling and they behave like CDM. Alternatively the WIMPs if produced non-thermally, it can be warm \cite{19-22}. In Ref.\textsuperscript{[20]} the authors showed explicitly that the power spectrum of this non-thermally produced WIMPs has a clear suppression at small scales. The non-thermally produced WIMP scenario will have some interesting properties for the indirect search of DM, because 1) compared with the light WDM the mass of the non-thermal WIMPs lies within the range of most high energy CR detectors, and 2) in contrast with the thermally...
produced WIMPs, the annihilation cross section of non-thermal WIMPs can be larger due to the lack of direct constraints from the relic density. We will discuss the possible γ-ray signatures from such non-thermal WIMP DM annihilation in this paper.

In this paper we focus on predicted DM annihilation signals from the Milky Way halo and its substructures based upon high resolution simulations of WDM in [23].

This paper is organized as follows. In Sec. II we briefly introduce the picture of the non-thermally produced warm WIMPs. In Sec. III we describe the numerical simulations used in this work and the DM density distributions for the smooth halo and subhalos according to the simulations. The signatures of γ-ray signals and detectability analysis are discussed in Sec. IV. Finally Sec. V is the conclusion.

II. NON-THERMALLY PRODUCED WARM WIMPS

The DM particles can be non-thermally produced by the decays of topological defects such as cosmic string [19, 20, 24]. For example, we consider a model with an extra U(1) gauge symmetry which is broken by the vacuum expectation value η of a scalar field S [19]. Cosmic strings will be formed during the symmetry breaking phase transition taking place at the temperature of \( T_c \sim η \). After the transition, the infinite long string network coarsens, and more closed string loops form from the reconnection of the long strings. The tension of the cosmic string is determined by \( μ \sim η^2 \). Cosmic string loops lose their energy dominantly through gravitational radiation. When the radius of a loop becomes to the order of the string width, the loop will self-annihilate into its constituent field, such as scalar boson \( S \). The DM particle \( χ \) can be produced by the decay of these heavy particles.

When the temperature of DM is higher than the freeze-out temperature \( T_χ (\sim O(\text{GeV})) \), DM particles produced by cosmic string loops still keep in chemical equilibrium with standard model particles. Only the DM particles produced below \( T_χ \) will contribute to the non-thermal DM relic density \( Ω_{NT} \). It is found that the non-thermal DM is mostly contributed by the loops decaying at \( T_χ \) (Eq. (A2)). Therefore the DM production process does not affect the big bang nucleosynthesis (BBN) results. Through adjusting the model parameters, the relic density of DM can also be naturally explained (for more details, see Appendix A).

In such scenario, DM particle \( χ \) may carry large initial momentum \( p_c \) due to the decay of the heavy particle. \( p_c \) can be written as \( p_c = α T_c \) where \( α \) is a numerical factor determined by detailed model. Here we define a typical variable \( r_c = a(t)p(t)/m_χ \) which is a constant during the cosmic evolution [23]. If we choose the cosmic scale factor at the present time \( a(t_0) = 1, r_c \) can be understood as today’s velocity of the DM particles if no structure formation. The comoving free-streaming scale \( R_f \) is given by [20]

\[
R_f = \int_{t_i}^{t_{EQ}} \frac{v(t')}{a(t')} dt' \sim 2r_c t_{EQ}(1 + z_{EQ})^2 \ln \left[ 1 + \frac{1}{r_c^2(1 + z_{EQ})^2} + \frac{1}{r_c(1 + z_{EQ})} \right],
\]

where “EQ” denotes the radiation-matter equality.

![FIG. 1: Linear matter power spectra of CDM (red, short-dashed), canonical light WDM (blue, long-dashed) and non-thermal warm WIMP (black, solid).](http://camb.info)

The free-streaming of DM particles will imprint on the late time structure formation. This effect can be simply seen by the matter power spectrum of DM. We use a modified version of CAMB [26] to calculate the matter power spectrum of the non-thermally produced DM scenario, shown in Fig. 1. Here we adopt \( r_c = 10^{-7} \). Note the mass of the non-thermal DM does not explicitly affect the calculation of the power spectrum because its effect can be cancelled by the initial momentum (see the definition of \( r_c \)). For comparison the power spectra for CDM and the canonical light WDM are also shown. The power spectrum of the canonical WDM corresponds to a sterile neutrino with mass \( \sim 2 \text{ keV} \), which is also the input power spectrum of the N-body simulation (see below Sec. III). We can see that a clear suppression of the power at small scales appears both for the light WDM and the warm WIMP scenarios. The free-streaming property makes the non-thermal DM behave similarly with WDM. Due to the similarity of the input power spectra of the light WDM and non-thermal warm WIMPs, we use the simulation results for the light WDM in the following discussion of the indirect detection of warm WIMPs.

\(^1\) http://camb.info
III. NUMERICAL SIMULATION RESULTS

In this section, we describe briefly numerical simulations used in this work and present the properties of the DM distribution based on the numerical simulations. The simulations used in this study are two matched ultra-high resolution simulations of a Milky sized DM halos run with different nature of DM models but with otherwise same numerical setup as well as cosmological parameters. For the CDM simulation, we use “Aq-A-2”, from the Aquarius Project [7]. In order to facilitate comparison of DM annihilation emission from cold and warm DM models, for the same halo, we further performed a high resolution simulation assuming WDM model by using the same phase in the initial density field as that of the “Aq-A-2” simulation but a different matter spectrum matching a particular WDM model. In the numerical calculation of this paper, we adopt a 2 kev sterile neutrino [27] as our WDM model which lies within bound of Lyα constraint [27]. The chosen WDM introduce a cutoff emerging at a wavenumber $k \sim 10h$ Mpc$^{-1}$ in the initial matter power spectrum, below which the power spectrum is well consistent with that of CDM [23]. In the scenario of non-thermal WIMPs, such as a heavy particle $S$ decaying into two WIMPs $\chi$, for $\chi$ around 100 GeV, it requires the mass of particle $S$ around 10$^8$ GeV [20]. In our simulation, the mass of the “particle” is $1.37 \times 10^4$ M$_{\odot}$, and the number of “particles” is larger than 100 million within $r_{200}$, the radius inside which the mean DM density is 200 times of the critical density. Therefore the lowest mass subhalos resolved in our simulation is $3 \times 10^5$ M$_{\odot}$ if requiring more than 20 “particles” for a subhalo. The total mass within $r_{200}$ of the halo is about $1.8 \times 10^{12}$ M$_{\odot}$. See Table 1 of Ref. [23] for the basic information of the simulations. For a more detailed description of our simulation, please refer to Ref. [23].

A. Smooth halo

The density profile of the smooth component of the simulated halo of the CDM simulation was analyzed in Ref. [23]. It was shown that the smooth halo density profile can be well fitted with an Einasto profile [20]

$$\rho(r) = \rho_{-2} \exp \left[ -\frac{2}{\alpha} \left( \left( \frac{r}{r_{-2}} \right) ^{\alpha} - 1 \right) \right],$$  \hspace{1cm} (2)

where $\rho_{-2} \approx 0.14$ GeV cm$^{-3}$, $r_{-2} \approx 15.7$ kpc and $\alpha \approx 0.17$ [28]. The local density of DM is then given as $\rho_0 \approx 0.44$ GeV cm$^{-3}$ at $R_0 = 8.5$ kpc. A higher local density compared with the canonical 0.3 GeV cm$^{-3}$ was also found in recent studies [30–32].

For the WDM halo the density profile of the smooth halo is essentially the same as that of CDM down to the numerical resolution limit of our simulation [32]. The expectation that a core may appear in the center of the halo for WDM due to phase space density constraint [34–36] is not clearly seen in the simulation, this is because the core size of the Milky Way sized halo is predicted to be smaller than resolution limit of our simulation and thus is not resolved. It was shown recently that a density core was indeed observed in WDM simulations, at a scale smaller than 100 pc for 1 – 2 keV WDM and halo mass $10^8 – 10^{10}$ M$_{\odot}$ [33]. For the Milky Way like halo the expected core will be even smaller, and the halo density profile will be indistinguishable from that of CDM halo, within the precision of sub-degree of the present $\gamma$-ray detectors. In this work we adopt the same equation (2) to describe the density profile of the smooth halo for WDM.

B. Subhalos

Based on the simulation results, we find 20529 gravitational bounded subhalos for CDM simulation and 219 subhalos for WDM$^2$ simulation within the virial radius of the main halo. The minimum mass of the resolved subhalo is found to be $\sim 3 \times 10^5$ M$_{\odot}$, and the maximum mass is about $10^{10}$ M$_{\odot}$.

We define the annihilation luminosity of a subhalo as $L_i = \int \rho_i^2 dV_i$. In the work we adopt the Navarro-Frenk-White (NFW, [39]) profile for the subhalos. The determination of the parameters of the NFW density profile from the simulated circular velocity profile can be found in the Appendix of Ref. [39]. For WDM subhalos we employ a constant density core with size $r_c \approx 0.03 \times \left( \frac{\sigma}{\text{kin}} \right)^{-0.5}$ kpc, where $\sigma$ is the velocity dispersion of the subhalo [40]. Beyond $r_c$, the density distribution is identical with NFW profile. The $\gamma$-ray flux from DM annihilation of this subhalo is then proportional to $L_i/d_i^2$, with $d_i$ the distance of the subhalo from Earth. To calculate $d_i$ of each subhalo, a random location of the solar system which is 8.5 kpc away from the halo center is chosen.

The mass-luminosity and mass-flux scattering plots of the subhalos are shown in Fig. [2]. From the mass-flux relation we see that in general, subhalos in CDM case are more brighter than that of WDM because of relatively lower concentration of subhalo in WDM comparing to CDM [23]. There are also fewer subhalos of WDM which can have comparable fluxes as that of CDM. Especially we find the most massive subhalos are usually not the brightest objects. The subhalos with masses $10^5 – 10^9$ M$_{\odot}$ have larger probability to give high fluxes [11].

For the CDM case it is expected that there should be a large number of unresolved substructures below the resolution limit of the simulation, which can extend to a mass comparable or even lower than that of the Earth, $10^{-6}$ M$_{\odot}$ [42, 43]. To include the contribution of unresolved subhalos we have to extrapolate the subhalos to lower mass, according to the statistical properties of the resolved subhalo distributions [3, 44]. We present the ba-
sic statistical results of the subhalos of CDM and WDM based on the simulations in the Appendix. For the WDM case, because free streaming length of the chosen WDM particle is as large as 200 kpc, the smallest dark matter halo expected to form in the model is therefore about $2.5 \times 10^7 M_\odot$, corresponding to $\sim 10^8$ particles in our simulation and hence are well resolved in our simulation. Thus we believe that our WDM simulation has resolved all subhalos and therefore has no unresolved subhalo component. There are some spurious subhalo formed in our simulation via artificial fragmentation of filaments as noted by Ref. [38], however we expect that contribution to the annihilation luminosity due to these spurious subhalos is small because of their low abundance. We do not consider them in the following analysis.

### C. $J$-factors

The $\gamma$-ray flux observed at the Earth from DM annihilation can be written as

$$\phi_\gamma(E_\gamma, \psi) = \frac{\rho_\odot^2 R_\odot}{4\pi} \frac{\sigma v}{2m_\chi} dE_\gamma \times J(\psi),$$

where $m_\chi$ is the mass of the DM particle, $\langle \sigma v \rangle$ is the annihilation cross section weighted with the velocity of DM particle, $\frac{dN}{dE_\gamma}$ is the $\gamma$-ray yield spectrum per annihilation. The dimensionless astrophysical $J$-factor, related to the DM density profile, is defined as

$$J(\psi) = \frac{1}{\rho_\odot R_\odot} \int_{\text{LOS}} \rho^2(l)dl,$$

where $\psi$ is defined as the angle between the observational direction and the Galactic center direction for observer at the Earth. The integral is done along the line of sight (LOS). Taking the detectors angular resolution into account the $J$ factor for a resolved subhalo is defined as

$$J_{\text{sub}}^i(\psi) = \frac{1}{\rho_\odot^2 R_\odot} \frac{L_i}{d_i^2} \times \frac{1}{2\pi \sigma^2} \exp \left[-\frac{(\psi - \psi_i)^2}{2\sigma^2}\right],$$

where $L_i$, $d_i$ and $\psi_i$ are the luminosity, distance and central direction of the $i$th halo. The exponential term on the right hand side corresponds to a Gaussian smooth with width $\sigma$.

Based on the numerical simulation of WDM we calculate the $J$ factor of the smooth halo and the subhalos. The skymaps of the $J$ factors of the smooth halo, resolved subhalos and the total result for WDM are shown in Fig. 3. The colorbar shows the value of log($J$). For resolved subhalos we employ Gaussian smoothing with $\sigma = 0.5^\circ$.

The skymaps of the CDM subhalos based on the simulation Aquarius has been given in Ref. [8]. To compare with the skymap of WDM subhalos given in this work we have also shown the skymaps of CDM in Appendix (see Fig. 10). From those two figures we can clearly see the differences between the CDM and WDM annihilation signals from subhalos. For CDM, there is a non-negligible diffuse component from the unresolved subhalos, especially at the directions far away from the Galactic center. The number of the potentially visible subhalos above the diffuse component is much higher for CDM than WDM. There is also difference in the Galactic center due to expected presence of a core in the WDM scenario. However, we may over-estimate the size of the core in this work compared with that found in the simulations [37]. The actual difference may be smaller.

The accumulative subhalo number which represents the subhalos with $J$ factor greater than some value $J_{\text{sub}}$ versus $J_{\text{sub}}$ is shown in Fig. 4. The different lines in each group represent the random choice of the location of the solar system in the halo, with distance fixed to be 8.5 kpc from the center. We can see that the number distribution of WDM is flatter than that of CDM. This is because in the CDM case the relative weight of smaller subhalos compared with larger ones is higher than that in the WDM case. The property presented in Fig. 4 if detectable, is useful to probe the nature of the DM particles.

IV. GAMMA-RAY SIGNALS

In this section we study the $\gamma$-ray signals from the warm WIMP annihilation. We will present the astrophysical $\gamma$-ray background and the detectability of the $\gamma$-rays from warm WIMP annihilation by Fermi.

A. Benchmark models of supersymmetric DM

For the warm WIMP, the annihilation cross section may be larger than that of cold WIMP which are constrained by the relic density of DM. However, considering the constraints from e.g., $\gamma$-rays and antiprotons, the cross section can not be arbitrarily large. The constraint from PAMELA antiproton data showed that the allowed boost factor$^3$ of neutralino-like DM should be less than 10 for $O(100)$ GeV DM [45]. The new constraints from Fermi observations of dwarf galaxies also gave an allowed boost factor of several for $O(100)$ GeV DM [8]. Taking the above contraints on the WIMP annihilation cross section into account, we give two explicit benchmark models to realize the cold and warm WIMP scenarios in supersymmetric DM models.

In the supersymmetric (SUSY) theory with R-parity conservation, the lightest neutralino, which is the combination of gaugino and higgsino, is a well-motivated candidate of DM [46]. In general, there are four parameter regions to obtain the correct thermal relic density of neutralino: (1) all the sfermions are light, neutralinos annihilate via $t$-channel sfermions exchange; (2) neutralinos scatter with sfermions with nearly mass degeneracy which is so-called “co-annihilation”; (3) $\tilde{\chi}_1^0$ has significant component of Higgsino or wino, with the main annihilation channel to heavy gauge boson or Higgs; (4) neutralinos annihilate via $s$-channel Higgs resonance with $2m_{\tilde{\chi}_1^0} \sim m_{A^0}$, or $m_{k^0}$, $m_{H^0}$. In the first region, the light sfermions are stringently constrained by recent LHC results [47, 48]. In the “co-annihilation” region, the neu-

$^3$ Defined as $\langle \sigma v \rangle / 3 \times 10^{-26}$ cm$^3$s$^{-1}$. 
TABLE I: Relevant parameters for the two benchmark models. The unit of \( m_0, m_{H_u}, m_{H_d}, m_{1/2}, A_0, m_{\chi^0_i} \) is GeV, and of \( \langle \sigma v \rangle \) is cm\(^3\)s\(^{-1}\).

|            | \( m_0 \) | \( m_{H_u} \) | \( m_{H_d} \) | \( m_{1/2} \) | \( A_0 \) | \( \tan\beta \) | \( \text{sign}(\mu) \) | \( m_{\chi^0_i} \) | \( \langle \sigma v \rangle \) |
|------------|---------|---------|---------|---------|---------|---------|---------|---------|---------|
| Warm WIMP  | 1200    | 1300    | 788     | 500     | -1000   | 40      | +       | 211     | \( 2.70 \times 10^{-25} \) |
| Cold WIMP  | 1200    | 1300    | 824     | 500     | -1000   | 40      | +       | 211     | \( 1.38 \times 10^{-26} \) |

The potential phenomenology problem of this region may be the large contribution to rare meson decay, such as \( B_d \rightarrow X_s \gamma \) and \( B_s \rightarrow \mu^+ \mu^- \), due to light pseudoscalar Higgs and large \( \tan\beta \). To avoid violating meson decay observations, some special parameters are needed to suppress total SUSY contributions from Higgs sector and chargino-squark sector.

We use the GALPROP\(^5\) code to calculate the Galactic diffuse \( \gamma \)-ray background. The propagation parameters adopted are: \( D_0 = 6.59 \times 10^{28} \) cm\(^2\)s\(^{-1}\), \( \delta = 0.30 \), \( v_A = 39.2 \) km s\(^{-1}\), \( \theta_0 = 3.9 \) kpc, according to the fit to the B/C data \[59\]. The injection spectra of nuclei are adopted as \( \gamma_1^n = 1.91/\gamma_2^n = 2.40 \) for rigidity below/above 10 GV, which can basically reproduce the recent measurements of proton and Helium spectra by PAMELA \[60\], as shown in \[61\]. Note, however, this simple injection model may not well describe the detailed hardening structures of the CR spectra above several hundred GV, or the difference between proton and Helium spectra (\[60\], \[62\], \[63\]). For CR electrons, the injection spectra are \( \gamma_1^e = 1.50/\gamma_2^e = 2.56 \) for rigidity below/above 3.55 GV as derived according to the pure background fit to the newest \( e^+e^- \) data \[64\]. Such a pure background component cannot explain the \( e^+e^- \) excesses revealed by several experiments \[64\], \[68\]. As illustrated in \[69\], the contribution to the total diffuse \( \gamma \)-rays from the extra atmospheric sources of \( e^+e^- \), e.g., pulsars, is always negligible in all regions of the sky. For the purpose of the current study, we think it is enough to employ such a rough background model. Finally the extra-galactic \( \gamma \)-ray background is adopted to be the Fermi measured results, \( \Phi_{\gamma G} \approx 5.89 \times 10^{-7}(E/\text{GeV})^{-2.44} \) cm\(^{-2}\)s\(^{-1}\)sr\(^{-1}\) GeV\(^{-1}\) \[70\].

We calculate the total \( \gamma \)-ray skymaps for the cold and warm WIMP scenarios based on the two SUSY benchmark models given the previous subsection. The total \( \gamma \)-ray skymaps above 10 GeV of both the astrophysical...
background and the DM contribution are shown in Fig. 5. The left panel is for cold WIMP and the right panel is for warm WIMP respectively. The detectability of the DM signal in presence of the astrophysical background will be discussed in the followings two subsections.

C. Gamma-rays from warm WIMP annihilation: Galactic center

![Gamma-ray spectra in 20° × 20° region around the Galactic center for cold and warm WIMP scenarios. Shaded region represents the expected background of the GALPROP model (see the text).](image)

Fig. 6 shows the expected γ-ray spectra of the WIMP annihilation in 20° × 20° region around the Galactic center. For comparison we also plot the calculated diffuse background described in Sec. IV. B. There are all-sky survey data of diffuse γ-rays from Fermi, available from the Fermi Science Support Center. It was shown that the GALPROP model could reproduce the observational data within a precision of factor 2. Therefore here we simply employ the model results for comparison. An uncertainty of 2 times of the GALPROP background is represented by the shaded region.

It is shown that for warm WIMP scenario we may expect larger flux of γ-rays in the Galactic center, simply due to a larger annihilation cross section of warm WIMPs. Up to now there is no clear evidence to show the existence of signals from DM in the Fermi data. However, we may expect that the warm WIMP scenario could have better detection perspective than the cold WIMP scenario.

D. Gamma-rays from warm WIMP annihilation: subhalos

Finally we discuss the detectability of DM subhalos. Fig. 7 shows the integral fluxes above 100 MeV of the DM subhalos for both the cold and warm WIMP models. With a factor of ∼ 20 times larger of the cross section for warm WIMP scenario, we can see that the fluxes of the most luminous subhalos in the two scenarios are comparable. Also shown in Fig. 7 are the upper limits (for 80%bb+20%τ+τ− case) of dwarf galaxies derived through 11-month observations of Fermi. The upper limits are in general higher than the model expected fluxes, which means the first year Fermi data may not be able to probe the DM subhalos of both the cold and warm WIMP models discussed here.

![Fig. 8 gives the results of the accumulative number versus the detection significance, defined as σ = N_{sig}/\sqrt{N_{bkg}}, for E > 10 GeV and 5-yr exposure of Fermi. Here the emission from subhalos within θ_{half}, angular radius containing half of the annihilation luminosity, is taken into account. The sky range to calcu-](image)

late the background number of events is adopted to be 
max(θ_{\text{half}}, θ_{\text{res}}), where θ_{\text{res}} \approx 0.1^\circ, is the angular resolu-
tion of Fermi-LAT at $E > 10$ GeV [73].

FIG. 8: The accumulative number of subhalos with signifi-
cance higher than $\sigma$, for energies $E > 10$ GeV and 5-yr expo-
sure of Fermi-LAT for the cold and warm WIMP scenarios.

Similar with Fig. 2 the number distribution for warm WIMP is flatter than that for cold WIMP. This is a sign-
ificance to distinguish these two scenarios. It is interesting
to note that the potential detectability for warm WIMP could be a little bit better (for high $\sigma$ ones) than that of
cold WIMP, although the number of subhalos are signific-
antly less. This is because the allowed cross section for
warm WIMP could be larger in principle. However, it is
generally difficult to detect the SUSY DM signals from subhalos with the Fermi detector, either for the cold or
the warm WIMP scenarios.

V. CONCLUSIONS

Since more and more evidence shows that the DM
tends to be “warm” instead of “cold” (e.g., [18]), it is necessary to investigate the possible consequence on
DM detections if it is indeed warm. For the canoni-
cal light WDM particle like the sterile neutrino, most of
the present DM detection experiments will be useless. Al-
ternatively the non-thermally produced warm WIMP
scenario [19, 20] might be interesting enough, for both
the cosmological structure formation and the detection
of DM particles. The large free-streaming of the DM
may help to solve the problems of CDM scenario at small
scale, and the WIMP particles are able to be detected
with most of the experiments searching for DM.

Based on the high resolution numerical simulations of
WDM structure formation, we study the possible $\gamma$-ray
signals from the annihilation of warm WIMPs in the
Milky Way. The Aquarius CDM simulations are also
employed to compare with the WDM results. We in-
vestigate the expected skymaps of the DM annihilation,
as well as the statistical properties of the subhalos. The
detectability with Fermi telescope is also discussed for
two benchmark SUSY models of warm and cold WIMP
scenarios respectively. Unfortunately we find that the
detectability of the warm WIMPs with current $\gamma$-ray ex-
periments is very poor. Nevertheless, it is interesting to
investigate the theoretically expected signatures of the
$\gamma$-rays from warm WIMP annihilation, in case that they
might be detected in future.

The major conclusions of this work can be summarized
as follows.

- Due to a suppression of structure formation in
  WDM scenario, subhalo is much less abundant in
  WDM scenario, resulting in a flatter accumula-
tive number distribution of $J$-factor and a diffe-
  rent $N(> J)$ vs. $J$ relation between warm and cold
  WIMP models.
- We find it is difficult to detect the subhalos with
  Fermi telescope, both for cold and warm WIMP
  scenarios. It is found that the detectability of
  warm WIMP could in principle be better than cold
  WIMP, because a moderately larger annihilation
  cross section is allowed for warm WIMP scenario,
  with a non-thermal production mechanism [24].
- For indirect WIMP search strategy, the Galactic
center would likely be prior to dwarf galaxies if
DM is made of warm WIMPs. For cold WIMPs
the $\gamma$-ray emission due to dark matter annihila-
tion from the Galactic center is polluted by the high
background and the subhalos have been believed to
be better targets for DM indirect searches. In the
warm WIMP case, however, the emission from the
Galactic center could be enhanced due to a larger
cross section, while the emission from dwarf galax-
ies is not as significantly enhanced because of the
decrease of the central DM density and concentration. For our benchmark models, the signal of the warm WIMP annihilation from the Galactic center will be around 20 times stronger than that of cold WIMPs, while it is comparable for subhalos. This might lead to a different detection strategy in case that WIMP is warm.

Appendix A: Relic density of non-thermal DM from cosmic string decay

Here we briefly discuss the non-thermal DM density from cosmic string decay. We assume the correlation length scale of the string is $\xi(t)$ in the friction dominated epoch. It can be given by $\xi(t) = \xi(t_c)(t/t_c)^{3/2} [74]$, where the initial length $\xi(t_c) \sim \lambda^{-1} \eta^{-1}$, $\lambda$ is the scalar self-quartic coupling. The production of cosmic string loops induces the energy loss of long strings. The number density of loops created by long strings can be evaluated by $[72, 76]$

$$\frac{dn}{dt} = \nu \xi^{-4} \frac{d\xi}{dt}, \quad \text{(A1)}$$

where $\nu$ is a constant of order 1. We assume each loop contributes $N$ DM particles.

Here we only consider the non-thermal DM particles from the decay of loops below the temperature $T_X$ (the corresponding time is $t_{th}$). For $m_X \sim 100 \text{ GeV}$, $T_X \sim \text{GeV}$. Then we can get the DM number density by integrating the red-shifted cosmic string loop number density

$$n^{NT}_X(t_0) = N \nu \int_{\xi(t_f)}^{\xi_0} \left( \frac{t}{t_0} \right)^{\frac{3}{2}} \xi^{-4} d\xi, \quad \text{(A2)}$$

where $t_f$ is the time at which cosmic string loops which are decaying at $t_f$ form. Since the loop density decreases sharply with time, we can see the DM density is mainly contributed by loops which decay right after $t_X$. It means the most of non-thermal DM particles are created at $t_X$ instantaneously.

According to the average radius of loop (formed at $t_F$) $R(t_F) \sim \lambda^{\frac{2}{3}} g_{F}^{\frac{1}{2}} G \mu M_{pl}^{\frac{2}{3}} t_F^{\frac{1}{6}}$, and the loop shrink rate $dR/dt = -\Gamma G \mu$ ($\Gamma$ is a constant $\sim 10 - 20$) [72, 76], we find $t_F \sim \lambda^{-\frac{1}{3}} g_{F}^{-\frac{1}{2}} \Gamma^{-\frac{1}{2}} M_{pl}^{-\frac{1}{3}} t_X^{\frac{1}{6}}$. Then the reduced number density of non-thermal DM particles from decays of cosmic string loops can be derived as $[19, 24]$

$$Y_X^{NT} = \frac{6.75}{\pi} N \nu \lambda^2 \Gamma^{-2} g_{F}^{1/2} g_{\xi} g_{\chi}^2 \frac{s - \frac{1}{2}}{\pi^2} \frac{M_{pl}^3}{T_c^4}. \quad \text{(A3)}$$

where $Y_X$ is defined as $Y_X = n_X / s$, $s = 2 \pi^2 g_s T^3 / 45$ is the entropy density, $g^*$ is effective degrees of freedom at the corresponding time. The DM relic density is related to $Y$ by $\Omega h^2 = 2.82 \times 10^8 Y_X (m_X / \text{GeV})$. It can be seen that the DM relic density dominated by non-thermal production, we can get the corrected DM relic density $Y h^2 \sim 0.11$ easily by choosing $\nu, \lambda \sim 1$, $\Gamma \sim 10$, $g^* \sim 100$, $m_X \sim O(10^2) \text{ GeV}$ and $T_c \sim O(10^3) \text{ GeV} [19, 24]$.

Appendix B: DM distribution from Aquarius simulation

Here we give the statistical results used for the extrapolation of the unresolved subhalos, based on the resolved subhalos from Aquarius CDM simulations. More results can be found in Refs. [7, 44].

We bin the luminosities $L_i$ of the subhalos with respect to mass and radius. The left panel of Fig. [8] shows the differential distribution of luminosity versus subhalo mass, $dL/dM$, and the right panel shows the spatial distribution of the luminosity, $dL/dV$. When doing this analysis we assume that $dL/dM$ is independent with the spatial distribution $dL/dV$ [8], so that we can use all the subhalos to derive both $dL/dM$ and $dL/dV$. The results for WDM are also shown in Fig. [8] for comparison.

The luminosity-mass relation $dL/dM$ can be fitted with a power-law function

$$dL/dM \propto M^{-1.14}. \quad \text{(B1)}$$

We can infer the cumulative luminosity distribution as $L(> M_{th}) \propto M_{th}^{0.14} - M_{max}^{0.14}$. For $M_{th} \ll M_{max}$ we have $L(> M_{th}) \propto M_{th}^{0.14}$. Note that this result is flatter than the mass dependence of the cumulative luminosity derived in [8] ($\propto M_{th}^{0.226}$). This may be due to the threshold effect when $M_{th}$ is close to $M_{max} \approx 10^{10} M_\odot$. For the spatial distribution of the luminosity $dL/dV$ we use an iso-thermal $\beta$ function

$$dL/dV \propto \frac{1}{[1 + (r/r_c)^{\beta}]} \quad \text{(B2)}$$

to fit the simulation results. The fitting parameters are $r_c \approx 54 \text{ kpc}$ and $\beta \approx 2.76$.

The unresolved subhalos in the CDM simulation is derived according to the fitting results of $dL/dM$ and $dL/dV$. The masses of unresolved subhalos are assumed to extend to $M_{min} \approx 10^{-6} M_\odot$ from $M_{res} \approx 3 \times 10^5 M_\odot$. The $J$-factor for unresolved subhalos is

$$J_{\text{subhalo}}(\psi) = \frac{1}{p_{c}^2 R_c} \int_{\text{LOS}} \left( \int_{M_{min}}^{M_{res}} d^2 L / dM dV \right) dL. \quad \text{(B3)}$$
FIG. 9: Differential luminosity-mass relation \( \frac{dL}{dM} \) (left) and spatial density of luminosity (right) for subhalos. Red circles are for Aq-A-2 CDM simulation, and black triangles are for Aq-AW-2 WDM simulation. Solid lines are the fitting results for CDM.

FIG. 10: Skymaps of the \( J \)-factors of the smooth halo (top-left), resolved subhalos (top-right), unresolved subhalos (bottom-left) and the total contribution (bottom-right) for CDM. This figure is a reproduction of the result given in Ref. \[8\].
