Abstract
This article reviews the water pollution by phosphate and sulfate anions, present in detergents and fertilizers; its consequences for the environment involves public health and food production. Mexican regulation for non-degradable detergents and wastewater must be updated, since in some countries these detergents are prohibited due to their negative impact on the environment.

Keywords: Water; Contamination; Phosphates; Sulphate

Introduction
Agricultural production according to the report of [1], is the main source of chemical contamination of water, due among other causes to the excessive use of fertilizers containing phosphorus, phosphates, nitrates and pesticides; also livestock activity through animal droppings whose runoff to bodies of water are another possible source of contamination with phosphorus and the use of detergents (phosphates and sulphates), within the livestock facilities.

Currently pastures for animal consumption and agricultural crops for human consumption must be produced in a sustainable and environmentally friendly manner. Such is the case of the studies carried out by Mexican researchers, whose results show that higher yields of the crops are produced with the use of bio-fertilizers.

Chemical Water Pollution
The fertilizers
The fertilizers used in agricultural production belong to the group of superphosphates, which are a source of contamination of groundwater, being dragged by rain and soil winds; since it is estimated that the crops absorb between 20 to 40% of the fertilizers applied and the rest is discarded causing water pollution, among other environmental phenomena such as acid rain and climate change. However, its use dates back to the 50’s. Mexico imports about 63% of the fertilizers used in agricultural production. So the development of bio-fertilizers for some years, has been a strategy to avoid environmental damage, caused by the excessive use of chemical fertilizers. Biofertilizers contain microorganisms that live in symbiosis with plants that help them feed and protect themselves from predators [2]. The best known are the mycorrhizal fungi that provide phosphorus to the plant and Bacillus bacteria (All-Taweil et al., 2009; Pooja et al., 2007). Phosphate solubilizing microorganisms [3], such as Fusarium oxysporum, Trichoderma aureoviridae, Aspergillus aculeatus, are considered as an alternative to replace synthetic fertilizers in agricultural fields (FAO, 2008).

Detergents
Cleaning agents or detergents, are chemical products intended for the washing of machinery and inputs in the livestock industry, which are used without any restriction; However, detergents contain chemical substances such as phosphates that reduce the hardness of water, favoring the function of surfactants, which help to modify the surface tension of water and can be: zwitterionic, amphoteric, anionic, cationic and non-ionic [4].

In 1940, detergents were introduced to the world market [5], which improved the cleanliness with respect to the products that contained soap as a base; sodium tripolyphosphate being its main ingredient [6], which represents a small portion of the phosphate market, while 85% is dedicated to the production of fertilizers [6]. Decades later he was assigned alterations in fauna in lakes with a
Phosphorus, phosphates and sulphates

The soluble phosphorus corresponds between 15 and 35% of the total of phosphates, the polyphosphates between 65 and 85% and in smaller proportion the condensed phosphates of high molecular weight and the organic phosphates, all of them differentiated by their chemical structure, which can be ortho-
\((\text{PO}_4^{3-})\), meta- \((\text{PO}_3^{2-})\), para- \((\text{P}_2\text{O}_7^{4-})\) or poly- \((\text{PO}_x^n)\) n-. Calcium phosphates have a dual behavior in water, because they are chemically long hydrocarbon chains at the end of which there is a cationic, anionic, amphoteric or polar group. By the number of hydrogens bound to the ionic element, mono- \((\text{Ca} (\text{H}_3\text{PO}_4)\)), di- \((\text{CaHPO}_4)\), tri- \((\text{Ca}_3(\text{PO}_4)_2)\) and tetra- \((\text{Ca}_3\text{P}_2\text{O}_8)\) are known. The main function of sodium tripolyphosphate (TPFS) is to improve the performance of detergents at low washing temperatures and with little dirt on clothes (Davidsohn & Milwidsky, 1978). Tripolyphosphate has the following functions: a) Due to its nature, it acts on the hardness of water due to the fact that it contains salts of \(\text{CaCl}_2\) and \(\text{MgCl}_2\) that cause crystalline deposits to remain in the fabrics and, like dirt and textiles, these salts can be contained TPFS reacts with these salts and forms phosphates that do not precipitate improving the cleaning and also avoiding the deposition of crystals in the washing machine. b) Increase the surface activity of the active washing compounds due to the increase in pH (with a buffer) so that the ions of the dirt and fabric increase their load and therefore their repulsion, increasing the washing performance. c) Another function is the deflocculation of fragments of clay into finer particles, preventing their redeposition in clothes by wearing them down. Related to this deflocculation property, it emulsifies oily materials [6]. Phosphorus \((\text{P})\), is a highly reactive chemical element that has multiple uses, is widely used in the detergent industry (Casañas et al., 2015). A content greater than 0.5 ppm of phosphates \((\text{PO}_4^{2-})\) causes foam, which prevents the entry of sunlight into the body of water, increasing the biological demand for oxygen \((\text{BOD})\) and within problems of eutrophication, dryness of lakes and death of aquatic species [6,7]. The toxicity of phosphates even at low concentrations causes a delay in the growth of plankton, increasing the concentration of methane \((\text{CH}_4)\) and amines in the water, because 1 g phosphate-phosphorus \(\text{PO}_4^{2-}\) affects the growth of 100 g of algae. When these algae die, the decomposition processes result in a chemical oxygen demand \((\text{DCO})\) of around 150 g, a parameter that is used to determine the quality of surface water bodies and water destined for irrigation. Sodium pyrophosphate \((\text{Na}_3\text{P}_2\text{O}_7)\) and sodium tripolyphosphate \((\text{Na}_3\text{P}_2\text{O}_{10})\) form stable and soluble complexes with the cations \((\text{calcium, magnesium and iron})\), with the disadvantage of being able to act as nutrients for some aquatic microorganisms creating an imbalance [6].

Toxicology studies have confirmed that detergents can cause eye irritation and respiratory tract, as well as alteration of the endocrine system, so the European Parliament issued a resolution on the deterrence of detergents in 2015, after having monitored more than 1000 detergents from various industries during 2012 and 2014 [9].

Sulfates \((\text{SO}_4^{2-})\)

The sulphate is a polyatomic ion with a sulfur as a central atom with four oxygen atoms around it, its chemical formula is \(\text{SO}_4^{2-}\). Sulfate is a surfactant, being responsible for the foam in detergents; The most common is sodium sulfate. Sulfates are salts produced by the combination of sulfuric acid with other substances, such as metals (copper sulfate).

The presence of sulfates in the water can be due to the leaching of the land, rain, or the discharge of wastewater. Most detergents contain sodium sulfonate, either straight or branched chain whose degradation is very slow, they are very abundant in nature and their content can vary, for example the concentration of iron sulphate present in the soil conditions the presence of sulfates in nearby rivers; the exploitation of pyrite in mines increases the sulfate ion in the water, mainly due to the oxidation processes that the mineral undergoes during its extraction. The alkyl-aryl sulfonates are substances obtained from aromatic compounds with an aliphatic chain attached to the aromatic nucleus. Some of the properties are their high property detergents, moisturizing power, foaming power and resistant to acids and alkalis.

The presence of sulfates in the water can be due to the leaching of the land, rain, or the discharge of wastewater. Most detergents contain sodium sulfonate, either straight or branched chain whose degradation is very slow, they are very abundant in nature and their content can vary, for example the concentration of iron sulphate...
The toxicity of the surfactant is determined by the absorption in the biological membranes and its penetration in the cell, the chemical structure of the chemical or surfactant since a hydrophilic head and a hydrophobic chain facilitates its entry, the hydrophobic part determines the ease in which it is inserted into the lipid bilayer of the cell membrane and the disturbance caused by the hydrophobic interactions once it is in the membrane causing its toxicity and causing the destruction of the function and structure of the bacterial membranes with the depolarization of the membrane, the decrease in the entry of nutrients and the excretion of substances by cellular metabolism [13].

The surfactants form heterogeneous structures consisting of two types of molecules, one with hydrophilic characteristics and the other with hydrophobic characteristics. The variation of each of them allows to improve the ability to wet, removes dirt particles that help the washing action and finally emulsifies, solubilizes and resuspends the dirt particles in the washing solution. The surfactants are classified by their ionic properties in water a) Cationic surfactants are composed of a positively charged nitrogen atom and at least one long hydrophobic chain, the most common being the quaternary ammonium compounds with a general formula R’R’’’R’’’’N+X−, where generally X− is a chlorine atom and R represents the alkyl groups; b) Anionic surfactants such as soap contain sodium, potassium or ammonium groups, such as sodium stearate. The surfactants are classified by their ionic properties in water a) Cationic surfactants are composed of a positively charged nitrogen atom and at least one long hydrophobic chain, the most common being the quaternary ammonium compounds with a general formula R’R’’’R’’’’N+X−, where generally X− is a chlorine atom and R represents the alkyl groups; b) Anionic surfactants such as soap contain sodium, potassium or ammonium groups, such as sodium stearate [14-20].

They are commonly used for their low manufacturing cost and are contained in virtually all types of detergents, the most suitable to be used are those that contain hydrophobic chains of 12-16 carbon atoms, being more degradable those that contain linear chains that branched. The most commonly used hydrophobic groups are: carboxylates (CnH2n+1COO−), sulfates (CnH2n+1OSO3−), phosphates (CnH2n+1PO4−OH) and sulfonates (CnH2n+1SO3−), where X− corresponds to Na, K or NH4. These detergents are very effective for the removal of oily particles. However, these detergents require other ingredients such as phosphates to prevent their deactivation by ions such as Ca2+ and Mg2+ that correspond to the hardness of the water.C) Non-ionic surfactants, prevent deactivation by water hardness and remove oily particles by solubilization and emulsification, are generally contained in liquid detergents and are sometimes mixed with anionic, are termed alcohol surfactants and ethoxylated alklyphenols. Another type of nonionic surfactants are the alkyl polyglycolides D) Amphoteric surfactants containing both anionic and cationic groups and are known as alkyl dimethyl betaine. Its cleaning function depends on the pH of the water solution, at acidic plhs it acts as a cationic surfactant and at alkaline pH as an anionic surfactant, its solubility depends on its isoelectric point and forms mixed micelles with other types of surfactants [9].

Conclusion

The chemical contamination of water causes an alteration in its composition, temperature, acidity and eutrophication. The signs of an eutrophication are: increase in algae aquatic plants, replacement of desirable fish by other unwanted species, production of toxins by certain algae, unpleasant odor, decrease in oxygen and fish mortality. The sanitary, chemical and toxicological safety of the residual water must be a requirement for its reuse since the sanitation processes are not designed to eliminate chemical substances or pathogenic microorganisms in their entirety, so it is necessary to implement innovative strategies in the municipal network of sewerage. In addition to including periodic monitoring plans, depending on their location and use, to strengthen environmental management programs in order to predict a possible risk. It is important to comply with the regulatory framework on field chemical substances in reusable waste for agricultural and livestock activities, which

requires sensitive analytical techniques that ensure their results. The population should be made aware of not spilling wastewater in the water channels as well as the use of biodegradable detergents (<15% phosphates), in order to avoid damage to public health and the environment.
