\begin{abstract}

The cosmic evolution of the metal content of the intergalactic medium puts stringent constraints on the properties of galactic outflows and on the nature of UV background. In this paper, we present a new measure of the redshift evolution of the mass density of C\textsc{iv}, $\Omega_{\text{CIV}}$, in the interval $1.5 \lesssim z \lesssim 4$ based on a sample of more than 1500 C\textsc{iv} lines with column densities $10^{12} \lesssim N(\text{CIV}) \lesssim 10^{15}$ cm$^{-2}$. This sample more than doubles the absorption redshift path covered in the range $z < 2.5$ by previous samples. The result shows a significant increase of $\Omega_{\text{CIV}}$ towards the lower redshifts at variance with the previously pictured constant behaviour.

\textbf{Key words:} intergalactic medium, quasars: absorption lines, cosmology: observations
\end{abstract}

1 INTRODUCTION

The cosmological mass density of C\textsc{iv}, $\Omega_{\text{CIV}}$, observed as a function of redshift is a fundamental quantity closely related to the metal enrichment of the intergalactic medium (IGM). Its apparent lack of evolution in the redshift interval $z \simeq [1.5,5]$ (Songaila 2001; Pettini et al. 2003; Boksenberg et al. 2003) is puzzling since both the physical conditions of the IGM and the properties of the ionizing background are thought to evolve between these epochs.

Remarkable efforts have been spent in recent years to extend the measure of $\Omega_{\text{CIV}}$ to redshift larger than 5 (Ryan-Weber et al. 2006; Simcoe 2006) where a decrease of the star formation rate density is observed (Bunker et al. 2008). If $\Omega_{\text{CIV}}$ is dominated by the metals produced in situ by the observed star forming galaxies, we would expect a decrease of its value at those redshifts. Vice versa, the value of $\Omega_{\text{CIV}}$ could remain constant if it reflects the metallicity of a diffuse medium pre-enriched at very high redshift. It should be noted, however, that this is a simplified scenario since, as redshift increases, the observed C\textsc{iv} absorptions likely trace gas in structures of decreasing over-density and also the ionizing spectrum evolves in shape and intensity. As a consequence, the behaviour of $\Omega_{\text{CIV}}$ could be different from that of $\Omega_{\text{C}}$ and of the mean IGM metallicity (see e.g. Schaye et al. 2003).

The most recent measurements of C\textsc{iv} absorptions in spectra of QSOs at $z \sim 6$ seem to indicate a downturn in the C\textsc{iv} mass density at $z > 5$ (Becker et al. 2004), though based only on 3 detected C\textsc{iv} lines.

At redshift $z \lesssim 4.5$, a fundamental measurement of $\Omega_{\text{CIV}}$ has been carried out by Songaila (2003, S01). However, the redshift interval $1.5 < z < 2$ is poorly sampled by the considered QSO spectra. A more uniform redshift coverage is provided by the sample of Boksenberg et al. (2003) although with fewer QSO spectra. Both analysis are consistent with a constant behaviour of $\Omega_{\text{CIV}}$ in the range $[1.5,4.5]$. At $z < 1$, recent results based on HST UV data (Cooksey et al. 2009) give $\Omega_{\text{CIV}} = (6 \pm 1) \times 10^{-8}$ corresponding to a $2.8 \pm 0.5$ increase over the $1.5 < z < 5$ values.

In this paper, we present a new measurement of $\Omega_{\text{CIV}}$ in the redshift range $[1.5,4]$ based on a sample of 25 high resolution, high signal-to-noise QSO spectra plus an additional sample of 8 QSO spectra from the literature.

The rest of the paper is organized as follows. The data are presented in § 2. In § 3 the analysis is carried out with the computation of $\Omega_{\text{CIV}}$. The results are discussed in § 4. Throughout this paper, we assume $\Omega_{\text{m}} = 0.26$, $\Omega_{\Lambda} = 0.74$ and $h \equiv H_0/(100 \text{ km s}^{-1} \text{ Mpc}^{-1}) = 0.72$.

2 OBSERVATIONAL DATA SAMPLE

The core of our sample is formed by the high resolution, high signal-to-noise QSO spectra already described in Saitta et al. (2007) and D’Odorico et al. (2008). Most of them were obtained with the Ultraviolet and Visual Echelle Spectrograph (UVES) (Dekker et al. 2000) at the Kueyen unit of the ESO VLT (Cerro Paranal, Chile) in the framework of the ESO Large Programme (LP): “The Cosmic Evolution of the IGM" (Bergeron et al. 2004).

In this work, 3 more QSOs were added to that sample, mainly to increase the redshift extension above $z \sim 3$.

\section*{The rise of the C\textsc{iv} mass density at $z < 2.5^*$}
UVES spectra of the QSOs: Q0055-269, PKS2000-330 and PKS1307-101, were downloaded from the ESO Archive and reduced with the UVES pipeline following the standard procedure. The continuum level was determined by interpolating with a cubic spline the region of the spectrum free from evident absorption features.

For all the QSO in the sample (see Table 1), the CIV forest was defined as the interval between the Lyα emission and 5000 km s\(^{-1}\) from the CIV emission to avoid the proximity region where most of the intrinsic systems are found. The absorption features present in this wavelength interval were identified inspecting the spectra by eye to look for the most common doublets (CIV, Mg II and SiIV). Then, other lines were identified testing their compatibility with the CIV, Mg II and SiIV redshifts. Finally, lines whose identity was still unknown after this operation, were associated with metal systems detected in the Lyα forest or recognized as part of other multiplets (e.g., Fe II).

The CIV doublets were fitted with Voigt profiles using the LYMAN context of the MIDAS reduction package (Fontana & Ballester 1993). A minimum number of components was adopted to fit the velocity profile in order to reach a normalized \(\chi^2 \sim 1\). The fit parameters for all the detected CIV lines are reported in Table 1. In the following, we will refer to CIV components or simply CIV lines meaning the velocity components in which every absorption profile has been decomposed. However, in order to compare our results with previous works and with data at lower resolution, we will work also with CIV systems formed by groups of components. CIV systems were defined in the following way: for each list of CIV components corresponding to a single QSO the velocity separations among all the lines have been computed and sorted in ascending order. If the smallest separation is less than \(dv_{\text{min}} = 50\) km s\(^{-1}\) (corresponding to the velocity separation adopted by SO1) the two lines are merged into a new line with column density equal to the sum of the column densities, and redshift equal to the average of the redshifts weighted with the column densities of the components. The velocity separation are then computed again and the procedure is iterated till the smallest separation becomes larger than \(dv_{\text{min}}\).

Our sample consists of 1023 CIV velocity components with column densities \(10^{12} \lesssim N(\text{CIV}) \lesssim 10^{15}\) cm\(^{-2}\) and of 508 CIV systems in the same column density range.

The CIV absorptions in the spectra of 19 of the QSOs forming our sample were already identified and fitted by Scannapieco et al. (2006) using the software package VPFIT. We refer to that paper for a careful analysis of the clustering properties of CIV lines and a comparison with the properties of SiIV, Mg II and FeII lines. Unfortunately, the authors did not publish the individual Voigt parameters of their fitting.

### 2.1 Additional data sample

In order to further increase the number of CIV lines and to extend the sample to higher redshift, we have considered the CIV lines fitted in 9 QSO spectra observed with the High Resolution Echelle Spectrometer (HIRES) at Keck at a resolution and signal-to-noise ratio similar to those of our spectra and reported in Boksenberg et al. (2005, BSR03). The fit with Voigt profiles was carried out by the authors with VPFTT. The main difference between LYMAN and VPFIT is that the number of components fitted to a given velocity profile is, in general, larger using the latter (see also the discussion in Saitta et al. 2007). This is seen also in the present case, in particular from the comparison of the CIV lines detected in the spectrum of the QSO B1422+231, which is the only object in common between the two samples. We find that in all cases the number of components found with VPFIT is larger or equal to that found with LYMAN. However, when the total column density of each absorption system is considered the difference between the two fitting procedures becomes negligible.

This is shown in Fig. 1 where the number of CIV components (upper panel) and the total column density of CIV systems (lower panel) obtained with the two fitting packages are compared. While the number of components is significantly larger in the fit by BSR03 the total column densities are most of the time in very good agreement.

The sample of BSR03 is formed by 577 CIV components and 302 CIV systems in the column density range \(10^{12} \lesssim N(\text{CIV}) \lesssim 10^{15}\) cm\(^{-2}\). The complete tables are available only in electronic format.

$N$(C IV) $\lesssim 10^{15}$ cm$^{-2}$. In the following, we will refer to our sample of C IV lines as Sample A and to the BSR03 sample as Sample B (excluding the lines of B1422+231, which are already in Sample A). The total sample is the sum of Sample A and Sample B. All the QSOs forming this sample are common redshift interval, 1.6 $\leq z < 3.6$ (see Fig. 2). The excess of low column density systems in BSR03 is due to their over-decomposition of the C IV velocity profiles with respect to our fit. A maximum likelihood fit to the data with column densities log $N$(C IV) $\geq 13$ (binned in Fig. 2 for display purposes only) to a power law of the form $f(N) = B N^{-\alpha}$, gives an index $\alpha = 1.71 \pm 0.07$ for sample A and $\alpha = 1.8 \pm 0.1$ for sample B. Both are in agreement with the result by S01 based on C IV systems defined in the same way. These are steeper than the Ellison et al. (2000) fit of 1.44 $\pm$ 0.05 based on the very high SNR spectrum of B1422+231 and extending the power law down to log $N$(C IV) $\sim 12.3$.

In order to estimate the incompleteness of our data for log $N$(C IV) $\leq 13$ we have performed the following simulations. Four fake C IV doublets have been generated for each spectrum in our sample, with column densities 12 $\leq N$(C IV) $\leq 13$ and redshift chosen randomly from the redshift range reported in Table 2. The $b$-values of the fake C IV lines were drawn at random from the observed distribution of $b$-values in our data. These fake C IV doublets were then added to the real spectra and searched for by the member of our team who had previously identified the real C IV lines. Given the visual, rather than automatic, character of our searches, only two such trials were performed. The results of these tests are collected in Table 3.

Figure 1. Upper panel: Number of components of the C IV absorption systems in the spectrum of B1422+231 as fitted by us (solid line) and by BSR03 (dashed line). Lower panel: Column densities of the C IV systems of B1422+231 computed by us (open dots) and by BSR03 (solid triangles).

Table 3. Results of incompleteness tests

| log $N$(C IV) | Fraction of detected C IV |

| 12.60        | 0.97                     |
| 12.78        | 0.97                     |
| 13.00        | 1.00                     |

3 DATA ANALYSIS

3.1 The C IV column density distribution function, $f(N)$

$f(N)$ is extremely sensitive to the velocity decomposition of absorption features, since it is defined as the number of lines per unit column density and per unit redshift absorption path, $dX$ (Tytler 1987). In the assumed cosmology, the redshift absorption path is:

$$dX \equiv (1 + z)^2[\Omega_m (1 + z)^3 + \Omega_{\Lambda}]^{-1/2}dz. \quad (1)$$

In order to compare with previous works, $f(N)$ has been computed for the C IV systems in samples A and B in the common redshift interval, 1.6 $< z < 3.6$ (see Fig. 2). The excess of low column density systems in BSR03 is due to their over-decomposition of the C IV velocity profiles with respect to our fit. A maximum likelihood fit to the data with column densities log $N$(C IV) $\geq 13$ (binned in Fig. 2 for display purposes only) to a power law of the form $f(N) = B N^{-\alpha}$, gives an index $\alpha = 1.71 \pm 0.07$ for sample A and $\alpha = 1.8 \pm 0.1$ for sample B. Both are in agreement with the result by S01 based on C IV systems defined in the same way. These are steeper than the Ellison et al. (2000) fit of 1.44 $\pm$ 0.05 based on the very high SNR spectrum of B1422+231 and extending the power law down to log $N$(C IV) $\sim 12.3$.

In order to estimate the incompleteness of our data for log $N$(C IV) $\leq 13$ we have performed the following simulations. Four fake C IV doublets have been generated for each spectrum in our sample, with column densities 12 $\leq N$(C IV) $\leq 13$ and redshift chosen randomly from the redshift range reported in Table 2. The $b$-values of the fake C IV lines were drawn at random from the observed distribution of $b$-values in our data. These fake C IV doublets were then added to the real spectra and searched for by the member of our team who had previously identified the real C IV lines. Given the visual, rather than automatic, character of our searches, only two such trials were performed. The results of these tests are collected in Table 3.

We found that we could recover essentially all C IV doublets as long as log $N$(C IV) $\geq 12.6$. For log $N$(C IV) = 12.3 a correction factor of 1.2 has been determined (31/38 fake C IV systems detected in the incompleteness tests). In the lowest column density bin, log $N$(C IV) = 12, 24 over 40 C IV lines have been identified, corresponding to a correction factor of 1.7. The average Doppler parameter of the undetected C IV lines is $(b) \sim 17.5$ km s$^{-1}$, while detected lines have $(b) \sim 9$ km s$^{-1}$. 
The evolution with redshift of \( \frac{dn}{dX} \) is a power law of the form \( f(N) = BN^{-\alpha} \) with index \( \alpha = 1.53 \) and 1.71, respectively (see text).

Extending the range of fitted data to our completeness limit, \( \log N(C\text{\textsc{iv}}) \geq 12.6 \), the maximum likelihood indexes become \( \alpha = 1.53 \pm 0.04 \) for sample A and \( \alpha = 1.61 \pm 0.07 \) for sample B, in agreement with the result by Ellison et al. (2001). If, the correction factors reported above are applied to the points of Sample A, their values increase slightly to coincide with the values in Sample B shown in Fig. 2. The corrected value of the lowest column density bin is still too low to be fitted with the previously derived power laws.

### 3.2 The number density of C\textsc{iv} lines, \( \frac{dn}{dX} \)

The evolution with redshift of \( \frac{dn}{dX} \) computed for C\textsc{iv} lines in Sample A is reported in the upper panel of Fig. 3. In particular, we have split our sample into weak and strong lines in Sample A (open dots) and Sample B (crosses) in the common redshift range 1.6 < \( z < 3.6 \). The bin-size is \( 10^{-3} N(C\text{\textsc{iv}}) \text{ cm}^{-2} \) and the error bars are \( \pm 1 \sigma \) based on the number of points in each bin. The dashed and dotted lines are power laws of the form \( f(N) = BN^{-\alpha} \) with index \( \alpha = 1.53 \) and 1.71, respectively (see text).

Figure 2. Comparison of the column density distribution function of C\textsc{iv} systems for Sample A (open dots) and Sample B (crosses) in the common redshift range 1.6 < \( z < 3.6 \). The bin-size is \( 10^{-3} N(C\text{\textsc{iv}}) \text{ cm}^{-2} \) and the error bars are \( \pm 1 \sigma \) based on the number of points in each bin. The dashed and dotted lines are power laws of the form \( f(N) = BN^{-\alpha} \) with index \( \alpha = 1.53 \) and 1.71, respectively (see text).

Figure 3. Upper panel: Redshift evolution of the number density of the C\textsc{iv} lines in Sample A divided into low column density (open dots, \( 12 \leq \log N(C\text{\textsc{iv}}) \leq 13 \)) and high column density (solid dots, \( 13 < \log N(C\text{\textsc{iv}}) \leq 15 \)) absorptions. Lower panel: Redshift evolution of the ratio between the number of high and low column density C\textsc{iv} lines.

and \( 2.3 < z < 3.5 \) (see Fig. 3). The obtained two-point correlation functions show a characteristic clustering scale \( r_0 \) (in redshift space) for the sample at high column densities which is about 1.5 – 2 times larger than for the low column density lines (\( \sim 850 \text{ vs. } 500 \text{ km s}^{-1} \) in the high redshift bin and 700 vs. 314 km s\(^{-1}\) for the low redshift bin, with 1 \( \sigma \) errors of about 150 km s\(^{-1}\) ). Converting these scales into comoving Mpc \( h^{-1} \) at a given redshift, it appears that the low column density sample has clustering properties similar to those of Lyman-break galaxies (LBGs) at \( z \sim 3 \) (e.g. Porciani & Giavalisco 2002), while large column density C\textsc{iv} systems are more strongly clustered and possibly sample denser environment and more massive objects. Adelberger et al. (2003) reached similar conclusions from the analysis of a large sample of LBGs observed in the fields of 23 high redshift QSOs.

### 3.3 The two-point correlation function of C\textsc{iv} lines, \( \xi(v, v + \Delta v) \)

We computed \( \xi(v, v + \Delta v) \) for the weak and strong C\textsc{iv} components and for two redshift intervals 1.5 < \( z < 2.3 \) and 2.3 < \( z < 3.5 \) (see Fig. 3). The obtained two-point correlation functions show a characteristic clustering scale \( r_0 \) (in redshift space) for the sample at high column densities which is about 1.5 – 2 times larger than for the low column density lines (\( \sim 850 \text{ vs. } 500 \text{ km s}^{-1} \) in the high redshift bin and 700 vs. 314 km s\(^{-1}\) for the low redshift bin, with 1 \( \sigma \) errors of about 150 km s\(^{-1}\) ). Converting these scales into comoving Mpc \( h^{-1} \) at a given redshift, it appears that the low column density sample has clustering properties similar to those of Lyman-break galaxies (LBGs) at \( z \sim 3 \) (e.g. Porciani & Giavalisco 2002), while large column density C\textsc{iv} systems are more strongly clustered and possibly sample denser environment and more massive objects. Adelberger et al. (2003) reached similar conclusions from the analysis of a large sample of LBGs observed in the fields of 23 high redshift QSOs.

### 3.4 The redshift evolution of the mass density of C\textsc{iv}

We used our sample of absorption lines also to compute the mass density of C\textsc{iv} as a fraction of the critical density today:

\[
\Omega_{C\text{\textsc{iv}}} = \frac{H_0 m_{C\text{\textsc{iv}}}}{c \rho_{\text{crit}}} \int N f(N) dN,
\]

where \( H_0 = 100 \text{ h} \text{ km s}^{-1}\text{Mpc}^{-1} \) is the Hubble constant, \( m_{C\text{\textsc{iv}}} \) is the mass of a C\textsc{iv} ion, \( c \) is the speed of light, \( \rho_{\text{crit}} = 1.88 \times 10^{-29} h^2 \text{ g cm}^{-3} \) and \( f(N) \) is the Column Density Distribution Function (CDDF). Since \( f(N) \) cannot
be recovered correctly for all column densities due to incompleteness and poor statistics, the integral in eq. 2 can be approximated by a sum:

$$\Omega_{\text{CIV}} = \frac{H_0 m_{\text{CIV}}}{c \rho_{\text{crit}}} \sum_i N_i(C\text{IV}) \Delta X,$$

(3)

with an associated fractional variance:

$$\left( \frac{\delta \Omega_{\text{CIV}}}{\Omega_{\text{CIV}}} \right)^2 = \frac{\sum_i [N_i(C\text{IV})]^2}{\left[ \sum_i N_i(C\text{IV}) \right]^2},$$

(4)

as proposed by Storrie-Lombardi et al (1996). Error bars have been computed also using a bootstrap technique to build 1000 samples of QSO spectra, based on the observed sample, for each redshift bin and determining the standard deviation of the resulting distribution of \( \Omega_{\text{CIV}} \) values. This estimate is always slightly larger (by a factor of \( \sim 1.5 \) or smaller) than the one based on eq. 4 and has been used as the reference one.

The value of \( \Omega_{\text{CIV}} \) significantly depends on the column density range over which the sum or the integration are carried out, and as a consequence on the resolution and SNR of the available spectra. To take this aspect into account, we have computed three sets of values to be compared consistently with different data in the literature.

\( \Omega_{\text{CIV}} \) obtained for the C\text{IV} components in Sample A with column densities \( 12 \leq \log N(C\text{IV}) \leq 15 \) is compared with the values reported in the original paper by BSR03 in Fig. 4. Our results confirm and strengthen the increasing trend with decreasing redshift of \( \Omega_{\text{CIV}} \) which was already present in the data by BSR03.
In order to carry out the comparison with the data set by S01, the most used in the literature for the redshift range [1.5, 4.5], \( \Omega_{\text{CIV}} \) has been computed from the C IV systems\(^3\) of the total sample with column densities \( 12 \leq \log N(\text{C IV}) \leq 15 \). In Fig. 7 these results are reported together with the value of S01 corrected for the assumed cosmology (they assumed Einstein-de Sitter) and with error bars derived from their plot and transformed to 1\( \sigma \). The present data sample represents an increase in the absorption redshift path of a factor 2.5 and 2 in the redshift bins [1.5,2.0] and [2.0,2.5] respectively, with respect to S01. Indeed, our estimate in the lowest redshift bin is \( \sim 4.5 \sigma \) larger than the previously accepted value, suggesting a trend of increasing C IV mass going to lower redshifts. The computed values with the associated errors are reported in Table 4.

We have not applied corrections to the values of \( \Omega_{\text{CIV}} \) due to the incompleteness of our observations for C IV lines with column densities \( \lesssim 12.6 \), since we estimated them to be less than 3 % (less than 1 % in the lowest redshift bin). This is due to the small correction factors determined in Section 3.1 and to the small contribution of low column density lines to the final values.

Recently, the determinations of \( \Omega_{\text{CIV}} \) have been extended to very low \( (z < 1, \text{ e.g. Cooksey et al. (2009)} \) and very high \( (z > 5, \text{ Ryan-Weber et al. (2004)} \) redshift. Observations in these redshift ranges are more difficult since the C IV transition moves to the UV and to the IR region of the electromagnetic spectrum, respectively. As a consequence, the estimates of \( \Omega_{\text{CIV}} \) are based on lower resolution and lower SNR spectra limiting the detectability of C IV lines to larger column densities. In order to study the evolution of \( \Omega_{\text{CIV}} \) in the whole redshift range between \( z \approx 0 \) and \( 6 \), we have carried out a third computation of the values of \( \Omega_{\text{CIV}} \) for C IV systems in the column density range \( 13.8 \leq \log N(\text{C IV}) \leq 15 \), changing the definition of the redshift bins in order to have comparable absorption redshift paths covered in each one of them. The column density lower boundary is the limit to which the higher (and lower) redshift surveys cited above are sensitive (being based on lower resolution and SNR spectra than those analysed in the present work). The results are shown in Fig. 7 where the point at \( z \approx 4.69 \) is the determination by Pettini et al. (2003) corrected for the considered column density range by Ryan-Weber et al. (2003). The plot shows clearly the smooth growth of the value of \( \Omega_{\text{CIV}} \) from the plateau at redshifts \( 3 - 5 \) to the local value, corresponding to an increase of a factor \( \sim 5 \). Our determinations are reported also in Table 4.

**Table 4.** \( \Omega_{\text{CIV}} \) for the systems in the total sample selected in the reported column density intervals

| \( z \) range | \( \Delta X \) lines | \( \Omega_{\text{CIV}} \) (×10\(^{-8}\)) | \( \delta \Omega \) (×10\(^{-8}\)) | \( [\delta \Omega]_{\text{boot}} \) (×10\(^{-8}\)) |
|--------------|-----------------|-----------------|-----------------|-----------------|
| 12 \( \leq \log N(\text{C IV}) \leq 15 \) | 1.5 - 2.0 | 12.61 | 148 | 10.0 | 1.8 | 2.7 |
| 2.0 - 2.5 | 28.11 | 211 | 5.0 | 1.0 | 1.4 |
| 2.5 - 3.0 | 19.82 | 161 | 3.2 | 0.7 | 0.8 |
| 3.0 - 3.5 | 13.91 | 132 | 2.4 | 0.4 | 0.6 |
| 3.5 - 4.0 | 7.60 | 78 | 3.7 | 0.7 | 1.0 |
| 13.8 \( \leq \log N(\text{C IV}) \leq 15 \) | 1.5 - 2.1 | 22.56 | 41 | 6.5 | 1.3 | 1.9 |
| 2.1 - 2.5 | 22.16 | 23 | 4.4 | 1.2 | 1.7 |
| 2.5 - 3.0 | 19.85 | 19 | 2.8 | 0.8 | 0.9 |
| 3.0 - 4.0 | 21.50 | 17 | 1.3 | 0.3 | 0.4 |

4 DISCUSSION

In this paper, we have presented a new determination of the cosmological mass density of C IV, \( \Omega_{\text{CIV}} \), at \( z = [1.5, 4] \) based on a large sample of high resolution, high signal-to-noise QSO spectra which more than doubles, with respect to previous measurements, the covered absorption path for \( 1.5 \leq z \leq 2.5 \). The main result of our calculation is that \( \Omega_{\text{CIV}} \) is no longer approximately constant in the considered redshift range, but shows a steady increase from \( z \sim 3 - 5 \) to \( z \sim 1.5 - 2 \). On the other hand, it appears that the C IV mass density is not evolving significantly from these redshifts down to the present epoch (Cooksey et al. 2009).

The value of \( \Omega_{\text{CIV}} \) for the column density interval \( 12 \leq \log N(\text{C IV}) \leq 15 \) can be converted into the IGM carbon content by mass, with the formula:

\[
Z_C \simeq \frac{\Omega_{\text{CIV}}}{\Omega_h} \cdot \frac{C}{\text{CIV}}
\]

where, \( \Omega_h = 0.0224 / h^2 \) (Pettini et al. 2008) is the contri-

---

\(^3\) We remind the readers that C IV systems have been built adopting a minimum velocity separation of 50 km s\(^{-1}\) as reported in S01.
bution of baryons to the critical density and C\textsc{iv}/C is the fraction of C which is triply ionized, which depends on the assumed ionizing background. Assuming the maximum relative abundance of C\textsc{iv}, that is C\textsc{iv}/C $\lesssim 0.5$, and the solar carbon over hydrogen abundance by mass $Z_\odot = 0.0029$ (Asplund et al. 2003), we obtain a lower limit at redshifts $[2.5, 4.0]$ of $Z_C \gtrsim 1.4 \times 10^{-6} = 4.9 \times 10^{-3} Z_\odot$ or $[\text{C/H}] \gtrsim -3.3$. At redshift $[1.5, 2.0]$; $Z_C \sim 4.6 \times 10^{-6} = 1.6 \times 10^{-3} Z_\odot$ or $[\text{C/H}] \gtrsim -2.8$, corresponding to an increase of a factor of $\sim 3$ with respect to the high redshift bin.

The metallicity measured at high redshift is in agreement with the result obtained at $z = 3$ by (Schaye et al. 2003) with the pixel optical depth method, in the case of over-densities above $\sim 10$. This is consistent with the fact that $\Omega_{\text{CIV}}$ traces mainly the metallicity of the over-dense regions in the proximity of galaxies and its redshift evolution is linked with that of the strong systems. (Simcoe et al. 2004) found a medianlicity $[\text{C}, \text{O}/\text{H}] \sim -2.8$ for the intergalactic gas at $z \sim 2.5$ with a method based on the direct detections of the absorption lines which takes into account also the upper limits. Re-normalizing our result to the solar abundances and the fraction of C triply ionized adopted by those authors (C\textsc{iv}/C $\lesssim 0.25$), we obtain $[\text{C/H}] \gtrsim -3.0$ consistent with their result.

The physical explanation for the redshift evolution of $\Omega_{\text{CIV}}$ can be explored with cosmological simulations. We will devote a subsequent paper to the comparison between observations and predictions of hydro-simulations with a detailed treatment of metal enrichment (Tescari et al., in preparation). In the following, we will briefly discuss the few predictions of $\Omega_{\text{CIV}}$ present in the literature and compare them with our results.

(Oppenheimer & Davé 2008, OD08) have run cosmological hydro-simulations of galaxy formation meant to reproduce the metallicity of the IGM, where metals are expelled from galaxies by momentum-driven winds (whose velocity is proportional to the dispersion velocity of the galaxies). Those winds are very effective in transporting the gas without heating it too much. Their fiducial simulation reproduces consistently the star formation rate of the Universe, the volume averaged metallicity of the IGM and the lack of evolution of $\Omega_{\text{CIV}}$ from $z \approx 5 \rightarrow 1.5$, as observed in the data available at the time. On the other hand, the predicted mass density of C increases by nearly an order of magnitude toward lower redshifts in the same redshift interval, due to the increase in the total metallicity of the gas. The constant behaviour of $\Omega_{\text{CIV}}$ is obtained by balancing the increase in C abundance with galactic winds. This form of feedback heats the IGM causing a decrease of the C\textsc{iv} ionization fraction. In particular, the peak of the C\textsc{iv} ionization fraction distribution as a function of over-density shifts toward larger over-densities as redshift decreases. This is consistent with the increase in the ratio between strong and weak C\textsc{iv} systems at lower redshifts shown in Fig.3 and the identification of strong systems with denser environment as deduced from the observed 2-point correlation function (see Section 3.3).

To conclude, none of the models proposed by OD06 predicts an increase of $\Omega_{\text{CIV}}$ toward lower redshifts. An improvement in the physics of the wind, plus the introduction of the AGB feedback, results in a slight increase of $\Omega_{\text{CIV}}$ in the ranges $z < 0.5$ and $z > 5$ leaving substantially unchanged the other values (Oppenheimer & Davé 2008, OD08).

An effect which has not been taken into account up to now is the evolution in the shape of the UV background due to the H\textsc{ii} re-ionization process expected at redshift $\sim 3$. Naively, due to the increase in the number of free hard photons (ionizing C\textsc{iv} into C\textsc{v}) at the end of the re-ionization epoch, we would expect a trend opposite to what is observed: a decrease of the amount of C\textsc{iv} after $z \sim 3$. However, the details of this process are still under study (e.g. (Bolton et al. 2009, Madau & Haardt 2000) and other factors should be accounted for properly: the decrease in the number density of QSOs going towards lower redshifts and the fact that at low $z$ the regions traced by the strong C\textsc{iv} absorbers (driving the evolution of $\Omega_{\text{CIV}}$) could be only mildly affected by the cosmic UV background.

The observed raise of the cosmic C\textsc{iv} mass density in the redshift range $1.5 \sim 2.5$ puts a strong constraints on the models describing the interplay between galaxies and their surrounding medium, suggesting that something is still missing in the physical implementation of galactic feedback.

ACKNOWLEDGMENTS

We would like to thank Eros Vanzella for his precious help in generating the synthetic C\textsc{iv} absorbers. We are grateful to the anonymous referee, whose comments and advice allowed us to improve significantly this paper. This research has been partially supported by ASI Contract No. 1/016/07/0 COFIS, INFN PD51 grant and PRIN MIUR. FC is supported by a fellowship by PRIN MIUR.
