Interpreting quantitative metabolome data is a difficult task owing to the high connectivity in metabolic networks and inherent interdependency between enzymatic regulation, metabolite levels and fluxes. Here we present a hypothesis-driven algorithm for the integration of such data with metabolic network topology. The algorithm thus enables identification of reporter reactions, which are reactions where there are significant coordinated changes in the level of surrounding metabolites following environmental/genetic perturbations. Applicability of the algorithm is demonstrated by using data from *Saccharomyces cerevisiae*. The algorithm includes preprocessing of a genome-scale yeast model such that the fraction of measured metabolites within the model is enhanced, and thus it is possible to map significant alterations associated with a perturbation even though a small fraction of the complete metabolome is measured. By combining the results with transcriptome data, we further show that it is possible to infer whether the reactions are hierarchically or metabolically regulated. Hereby, the reported approach represents an attempt to map different layers of regulation within metabolic networks through combination of metabolome and transcriptome data.

Introduction

One of the goals of systems biology is to obtain overall quantitative description of cellular systems. This is currently not achievable as the number of components and interactions involved in these systems is quite large resulting in a very large parameter space. Thus, methods are required to reduce the dimensionality and particularly identify key regulatory points in the many different cellular processes. Metabolism is a good starting point to develop such analysis methods as it is studied in great detail and well annotated. Furthermore, genome-scale metabolic models have been developed for many different cellular systems (Edwards and Palsson, 2000; Förster et al., 2003; Sheikh et al., 2005), and besides their use for simulation of cellular function (Edwards et al., 2001; Famili et al., 2003; Price et al., 2004), these models can serve as scaffolds for analysis of genome-scale biological data (Covert et al., 2004; Borodina and Nielsen, 2005). This has been demonstrated recently for analysis of transcriptome data, where the use of genome-scale metabolic models enabled identification of coregulated sub-networks and reporter metabolites (Patil and Nielsen, 2005). Although transcriptome data provide an overview of the global regulation in the metabolism, understanding of cellular physiology is incomplete without knowledge of metabolome, owing to the high connectivity in metabolic networks and inherent interdependency between enzymatic regulation, metabolite levels and fluxes (Nielsen, 2003). Metabolites, acting as intermediates of biochemical reactions, play a crucial role within a living cell by connecting many different operating pathways. Metabolite levels are determined by the concentrations and the properties of the surrounding enzymes, making their levels a complex function of many cellular regulatory processes in different dimensions. Thus, the metabolome represents a snapshot of the functioning metabolism of the cell and hence provides valuable information about regulation of several different cellular processes (Villas-Bôas et al., 2005c). Consequently, in recent years, there has been increased focus on analysis of the metabolome (Sumner et al., 2003; Bino et al., 2004; Villas-Bôas et al., 2005c). Even though traditional data analysis methods like principal component analysis, clustering analysis and chemometrics have shown to be efficient for analysis of this kind of data (Raamsdonk et al., 2001; Allen et al., 2003), there are some limitations with these methods for uncovering the underlying biological principles (Weckwerth et al., 2004). Furthermore, there are still only few examples of studies on the
use of metabolome data to understand regulatory principles in metabolism.

Functional analysis of cellular metabolism and in particular integration of metabolome data with other omics-data demands (semi-)quantitative measurements of key metabolites. However, a problem with metabolomics is the scarcity of targeted quantitative data, and often metabolome analysis is (at best) semiquantitative even though there is a trend towards more quantitative analysis (Nielsen and Oliver, 2005). Although it is currently not yet possible to quantify all the metabolites in a cellular system (Fernie et al, 2004; Goodacre et al, 2004), a high-throughput GC–MS method that allows semiquantitative identification of several metabolites in Saccharomyces cerevisiae was recently developed (Devantier et al, 2005a; Villas-Bôas et al, 2005a). In the latter studies, the levels of 52 unique metabolites (out of 584 reported unique metabolites in the genome-scale yeast model; Förster et al, 2003) were determined in genetically different yeast strains under different environmental conditions. Specifically, metabolites playing important roles in the central carbon metabolism and amino-acid biosynthesis could be identified.

In order to understand the regulatory principles underlying the changes in metabolite levels, we developed an algorithm that enables integration of such quantitative metabolome data with genome-scale models by using a graph theoretical representation of the metabolism. We demonstrate the application of this algorithm for the metabolome data reported by Villas-Bôas et al (2005a) and Devantier et al (2005a). We use the significance of changes in the metabolite levels to identify reporter reactions around which the most significant coordinated metabolite changes are observed. Reporter reaction analysis is an attempt to infer the differential reaction significance based on metabolite measurements, and hence provides a basis for understanding the underlying cellular processes responding to the perturbations. We further demonstrate that through combination with transcriptome data, reporter reactions may provide clues on whether regulatory control at a given reaction node is at the metabolic level or at the hierarchical level.

**Results and discussion**

**Model preprocessing**

Owing to the large chemical diversity of the metabolome, there is currently no single analytical method that enables analysis of the complete metabolome. Even the best analytical methods reported to date for metabolome analysis therefore only cover a small fraction of the metabolites present in genome-scale metabolic models. The unavailability of data for a large number of metabolites is one of the major problems associated with mapping (and hence integration) of metabolome data on to genome-scale metabolic networks. In order to overcome this fundamental problem, we preprocessed the genome-scale model of Förster et al (2003) so as to obtain a reduced model, where the fraction of experimentally measured metabolites was enriched. This processing was carried out by systematically eliminating unmeasured metabolites from the metabolic network. We note that the model preprocessing is dependent on the metabolome data that are available, and the preprocessing will have to be carried out for each case. However, following the flow-chart depicted in Supplementary Figure 1, this preprocessing is relatively straightforward and can easily be carried out also for other metabolic networks.

The yeast genome-scale model includes three compartments (mitochondria, cytosol and external space) with 844 metabolites (559 cytosolic, 164 mitochondrial, 121 external) and 1175 reactions (Förster et al, 2003). Within the context of this model, metabolites present in more than one compartment are treated as if they are different entities in each compartment. However, the experimental data used in this analysis (and most of the data sets available to date) can only differentiate between extracellular and intracellular space. As metabolite levels in different cellular compartments are not available, the cytosolic/mitochondrial compartmentation of the model was removed and corresponding metabolites were represented as one, with their corresponding reactions conserved. Also, there are a number of duplicate reactions owing to the presence of isoenzymes in the model, and these reactions were lumped into single reactions, as metabolome data alone do not provide information that enables distinction between the operations of different isoenzymes. As a result, the ‘processed’ model (uncompartmented model, UNCOMP) consists of 677 metabolites (559 internal, 118 external) with 725 reactions, including transport reactions. With this model, the experimental data used here amount to about 12% of these 677 metabolites (52 internal, 32 external).

Enzyme subsets are enzymes that always operate together in fixed flux proportions at steady state (Pfeiffer et al, 1999; Schuster et al, 2002), often representing enzymes in linear pathways. Accordingly, the intermediate metabolites in enzyme subsets can be assumed to be similarly affected by the perturbations. UNCOMP was further reduced in size by using METATOOL 4.3 (Pfeiffer et al, 1999; Dandekar et al, 2003) and thus representing each enzyme subset as a single reaction. The resulting model (enzyme-subset model, ENZSUB-1) consists of 563 metabolites and 590 reactions and it has about 15% of the metabolites measured within the data used. As the removal of the metabolites in linear pathways also led to the omission of six measured metabolites, the reactions containing these metabolites were restored back into the ENZSUB-1 model. To further increase the fraction of the measured metabolites, potentially inactive (or potentially low flux) reactions were removed. This was carried out by using flux balance analysis (FBA) (Varma and Palsson, 1994; Kauffman et al, 2003) for simulation of fluxes at specific environmental conditions used in the experiments (aerobic and anaerobic batch cultivation in glucose-limited minimal media). The ENZSUB-1 model was used to simulate the fluxes with the objective of optimum growth. Then, the maximum and the minimum flux for each reaction in the model were obtained by constraining the specific growth rate between its optimum value and 50% of the optimum. Reactions that had zero flux in the FBA analysis (at both optimum values) were considered as potentially invariant between the studied perturbations and thus omitted from the ENZSUB-1 model. The resulting model had 349 reactions involving 267 metabolites. The here-used FBA-based approach for model reduction does not necessarily imply that the eliminated reactions are inactive and that the metabolites involved in
these reactions not present in the cell. However, it is assumed that as these reactions are likely to carry very low fluxes under the studied conditions, the associated metabolite pools are likely to be weakly affected because of the changes in the fluxes through these reactions. Although this approach is useful, the assumption is not fool-proof as we indeed found certain measured metabolites that were intermediates in pathways with zero fluxes (pimelic acid, PIMExt, myristic acid, C140xt, trans-4-hydroxy-L-proline, itaconate, nicotinate, 4-aminobenzoate, THMxt). The first six of these metabolites were detected as ‘invariant’ by the FBA approach owing to the fact that these metabolites are not connected to the overall network (Förster et al., 2003). However, here we restored back reactions involving these measured metabolites, and the resulting model comprised a total of 285 metabolites participating in 361 reactions (Supplementary Figure 1). Even though certain reactions may be removed from the analysis by using this approach, the algorithm will still correctly identify reporter reactions, given the metabolome data set. The resulting metabolic network, ENZSUB-2 model, was substantially enriched in terms of the content of measured metabolites (now accounting for about 30%).

In order to further focus the analysis only on reactions involving measured metabolites, ENZSUB-3 was constructed by keeping only reactions that involved at least one measured metabolite. Additionally, only one member of the NADH/NAD⁺, NADPH/NADP⁺, FADH₂/FAD⁺ cofactor pairs, when available, was retained in the remaining reactions as the levels of members of each pair were assumed to be interdependent. The resulting metabolic network, ENZSUB-3, included a total of 178 metabolites participating in 139 reactions, which corresponds to more than 47% of the available quantitative metabolome data (Supplementary Figure 1). The 139 reactions included in the model are given in Supplementary Table 1.

The significance of the change in the levels of metabolites between any two conditions was calculated by applying a 

---

**Figure 1** Reporter reaction algorithm to identify differential reaction significance by integrating metabolome data with metabolic networks. Quantitative metabolome data obtained from perturbation experiments are interpreted in terms of significance of change, and mapped onto the stoichiometric network, which is represented as bi-partite undirected graph, to identify reporter reactions.
statistical test (see Materials and methods). However, it is difficult to deduce which reactions in the cell are affected most by only judging the significance of the change in metabolite levels, as the number of the metabolic reactions in the cell is high and one metabolite usually appears in more than one reaction. Thus, we calculated a normalized Z-score for each reaction based on the z-values of its neighboring metabolites (P-values of individual metabolites were converted to Z-scores by using inverse normal cumulative distribution function; see Materials and methods). Here we assume that the calculated reaction Z-scores can be regarded as an indicator of the significance of how the reactions respond to the studied perturbation at metabolic level. This assumption is based on the fact that metabolite levels are governed by changes in fluxes and enzyme activities (Nielsen, 2003). Reactions exhibiting significant changes (typically $Z > 1.28$, corresponding to $P < 0.10$) for the perturbations analyzed were identified by using the graph representation of the derived metabolic model, ENZSUB-3, and are listed in Tables I and II. A loose cutoff was deliberately chosen, as we did not want to be too biased in the light of the fact that measurements were not available for all of the metabolites in the model, and thus the resultant $P$-values are in fact, in general, shifted to high values owing to randomly selected $P$-values for those unmeasured metabolites.

**Effect of an altered redox metabolism and oxygen availability**

As a first demonstration of our approach, we considered data from metabolome analysis of two different S. cerevisiae strains, a wild-type laboratory strain (CEN.PK.113-7D) and a redox-engineered strain, which was carried out in batch cultures under two different environmental conditions (aerobic and anaerobic) in standard mineral media with glucose as the sole carbon source (Villas-Bôas et al., 2005a). The redox-engineered strain carrying a deletion of the NADPH-dependent glutamate dehydrogenase encoded by GDH1 and an overexpression of the NADH-dependent glutamate dehydrogenase encoded by GDH2 was constructed by dos Santos et al. (2003). Three different perturbations were analyzed here: genetic change under both aerobic and anaerobic conditions (wild-type versus redox-engineered strain), and environmental change for the wild-type strain (aerobic versus anaerobic). As it was reported that sample-to-sample variability exceeds flask-to-flask variability, replicate samples from different shake flasks were treated equivalently (Villas-Bôas et al., 2005a). Accordingly, the metabolome data set includes around 15 intracellular and nine extracellular replicates for each experimental condition. The data set used in this study is available in Supplementary information as normalized abundances of GC–MS peaks.

Comparison of the wild-type and mutant strains revealed that the genetic changes do not alter the basic growth characteristics in aerobic (dos Santos et al., 2003) and anaerobic (Nissen et al., 2000) batch cultivations. Our approach, however, captures the associated changes in different cellular pathways, by identifying a number of significantly affected reactions due to these perturbations. The detected reactions (Table I) belong to many different amino-acid pathways, indicating a widespread effect of the mutation on the cellular metabolism. The present integrated approach also differentiates between the genetic perturbation under aerobic and anaerobic conditions, as there are reactions that are specific to each condition.

Genetic perturbations (wild type versus redox engineered) used in the present study are directly related to a changed redox metabolism. Environmental perturbation (aerobic

The number of measured metabolites and the total number of metabolites for each reaction are also given in parentheses. The explicit form of the reactions can be followed from Supplementary Table I.

Reactions specific to each perturbation are given in bold letters.

ES means that the corresponding reaction is an enzyme subset consisting of a combination of more than one reaction.

's in some of the reaction names stands for 'secretion', indicating that they are secretion reactions.
versus anaerobic) is, however, also associated with a changed redox metabolism owing to the direct effect of oxygen availability on the operation of the TCA cycle and the pentose phosphate pathway, and hence on the redox state of the cell. This is also reflected in the identified reporter reactions, as a number of common significantly changed reactions are observed for the two different types of perturbations (Table I and Supplementary Table 2).

The glutamate decarboxylase reaction (GAD1) appears as a significantly changed reaction specific to the environmental perturbation of the wild-type cells, which implies a major role of this reaction during respiratory growth (Table I). Indeed, it was reported (McCammon et al., 2003) that the defects in any of the 15 TCA cycle genes, associated with the slowing down of the respiratory metabolism, result in a substantial decrease in the mRNA levels of GAD1, which is in agreement with our findings. GAD1 constitutes the first step of the glutamate biosynthesis, which is active in S. cerevisiae. Examination of the Z-scores of reactions involving glyoxylate for all the analyzed perturbations revealed that AGX1 (reaction of enzyme encoded by YFL030w), which enables synthesis of glyoxylate from glycine, has much higher scores for all the perturbations compared to the reactions of the glyoxylate pathway (ICL and MLS) (Figure 2B). Thus, our analysis supports the presence of an alternative pathway catalyzed by AGX1 leading to the biosynthesis of glyoxylate from glycine.

Reporter reaction analysis also identifies that the genetic perturbation results in metabolic changes around the genes that are perturbed (Figure 2C). Thus, the reaction responsible for the overexpressed gene in the redox-engineered strain, GDH2, has a significant Z-score for the genetic perturbation under aerobic condition. It should be mentioned that a genetic perturbation of a gene should not necessarily result in that the corresponding reaction comes out as a reporter reaction, as certain genetic perturbations may lead to only small changes in metabolite levels. However, in this case, there are two genetic modifications around α-ketoglutarate and glutamate (deletion of GDH1 and overexpression of GDH2) that lead to identification of GDH2 as reporter. For the genetic change under anaerobic conditions, the detected significance of GDH2 is comparably lower. However, an indirect effect of the genetic modification in the glutamate biosynthesis can be observed.

Although the glyoxylate cycle is generally believed to be repressed during growth on glucose, Villas-Bôas et al. (2005b) found that an alternative pathway for glyoxylate biosynthesis is active in S. cerevisiae. Examination of the Z-scores of reactions involving glycolate for all the analyzed perturbations revealed that AGX1 (reaction of enzyme encoded by YFL030w), which enables synthesis of glyoxylate from glycine, has much higher scores for all the perturbations compared to the reactions of the glyoxylate pathway (ICL and MLS) (Figure 2B). Thus, our analysis supports the presence of an alternative pathway catalyzed by AGX1 leading to the biosynthesis of glyoxylate from glycine.

*Reactions specific to each perturbation are given in bold letters.
from the presence of transaminase activity associated with some of the identified reporter reactions for this perturbation (conversion of glutamate to α-ketoglutarate by ALT, LEUsynES, PHEsynES, VALsyn, SERsynES; Table I and Supplementary Table 2). On the other hand, the aerobic–anaerobic shift for the wild type gives rise to nearly the same Z-score for GDH2 reaction as the genetic perturbation under aerobic conditions. One explanation for this similarity in behavior would be that oxygen availability may have a direct effect on glutamate dehydrogenase genes; that is, cessation of oxygen uptake or oxygen availability may have a direct effect on glutamate metabolism.

Similarly, the Z-scores of key reactions involving oxaloacetate suggest that these reactions are mainly affected in the redox-engineered strain under aerobic conditions (Figure 2E), and AAT, a transamination reaction leading to the conversion of oxaloacetate to aspartate, appears to be the key reaction where oxaloacetate is involved. There are no literature data available about the effect of the genetic perturbation on this metabolic reaction, but as the genetic perturbation results in a changed ratio of glutamate to 2-oxoglutarate (Villas-Bôas et al., 2005a), it may have affected this important transamination reaction.

**Effect of very high-gravity fermentation**

As a second demonstration of our approach, we used metabolome data from two different S. cerevisiae strains, a laboratory strain (CEN.PK.113-7D) and an industrial strain used for fuel ethanol production (hereafter termed as ‘Red Star’). For both strains, the data were obtained from anaerobic batch cultures under two different cultivation conditions: exponential growth in glucose-containing standard mineral media and the stationary phase in maltodextrin-containing media and the stationary phase in maltodextrin-containing...
very high-gravity (VHG) mineral media (Devantier et al., 2005a). Environmental perturbations obtained through variation in the media were analyzed here for each strain. The intracellular metabolome data set includes four replicates for the standard medium and eight replicates for the VHG medium. The extracellular metabolome data set has six replicates for each condition. The complete data set is available in Supplementary information.

As for the first case study discussed above, the two media perturbations analyzed revealed the same trend for the glyoxylate reactions, pointing to substantial regulation of the AGX1 reaction node in both perturbations (data not shown). In case of the glutamate metabolism, all the reactions have noticeably higher Z-scores, except GDH2, implying that this pathway is highly affected by VHG-associated media changes. All of the TCA cycle reactions shown in Figure 2D have very low Z-scores, in accordance with the fact that the cycle is barely operational under any of the experimental conditions studied (anaerobic fermentations). For reactions involving oxaloacetate, AAT again appears to play the major role as observed in the first data set, in parallel with the graph shown in Figure 2E.

The reaction governed by Gadlp, which catalyzes decarboxylation of glutamate—a reaction that is generally considered to be associated with stress—is found to be significantly changed in both strains when the media were changed (Table II). A noticeably lower score was obtained for comparison of the two strains grown on the standard medium (results not shown), which shows that the standard medium imposes less stress compared with the VHG medium where sugar and ethanol stresses are predominant. The appearance of all reactions (GAD1, UGA03) involved in the glutamate catabolic pathway as reporter reactions when the media are perturbed (Table II) points to the fact that this perturbation has a major effect on the amino-acid metabolism, and probably also on the redox balance in the cell. The results of transcriptome analysis for the same strains in standard and VHG media (Devantier et al., 2005b) indicate that the strains have differences in their redox balancing, confirming our finding.

A large number of transport reactions were found to have significant Z-scores (Table II). GC–MS analysis of extracellular metabolites in the VHG medium revealed many more metabolites compared to what is found in the standard medium, explaining the appearance of transport reactions as significant. The here-reported algorithm allowed us to identify and quantify the secretion reactions which are mostly affected from the media change, by integrating both intracellular and extracellular measurements to the reaction network. Secretion of a number of amino acids (glutamate, aspartate, proline, alanine and glycine), and succinate, pyruvate and lactate is commonly and significantly regulated in response to media perturbation for both the laboratory and the red star strain. On the other hand, detection of strain-specific secretion patterns (valine, citrate and α-ketoglutarate; Table II) points to differences in operation of the metabolic network in the two strains, possibly arising from the difference in the redox metabolism of the two strains.

As the change in the fermentation medium led to ethanol and osmotic stress for both strains (Devantier et al., 2005a), it is not surprising that many of the reactions are shared in the identified lists for the two strains in the media comparison (Table II). Transcriptome analysis of this data set revealed that a substantial part of the significantly changed genes were involved in protein synthesis and amino-acid metabolism (Devantier et al., 2005b). Thus, amino-acid pathway reactions detected by our analysis (Table II) are in accordance with the transcriptome data. Absence of amino-acid synthesis in VHG media owing to the cessation of growth in the stationary phase can be a possible cause of the observed differences.

Integration of metabolome data with transcriptome data for understanding regulation

For the latter case study, where the effect of a VHG medium was analyzed on the metabolome of laboratory and industrial strains, a genome-wide expression analysis was also performed (Devantier et al., 2005b). This basically enables further evaluation of mode of regulation for the different reactions in the reduced metabolic network. ter Kuile and Westerhoff (2001) introduced the concept of metabolic regulation and hierarchical regulation, where the first indicates that regulation of flux is at the level of enzyme kinetics, that is, through changes of the metabolite levels, and the second indicates that regulation of flux is at the level of enzyme production/activity (transcription/translation/post-translational modification). As both metabolite data and transcription data are available for this case study, we looked into whether it was possible to identify the type of regulation at the individual reaction level. A major obstacle for this kind of analysis is, however, that we do not have information about changes in fluxes for the analyzed conditions, and such data would also be difficult to obtain. Although there are efficient methods for obtaining data on the metabolic fluxes in the central carbon metabolism (Nielsen, 2003), it is difficult to get good estimates for the fluxes in all pathways of the metabolic network analyzed here, and even though the fluxes can be calculated by using FBA, this method is not well suited to give precise estimates for the actual fluxes in networks where there are redundant pathways. In order to proceed with analysis, we therefore assumed that whenever there was a coordinated significant change in metabolite levels around a reaction, then it is very likely that the flux through this reaction is also changing. However, there is no guarantee that the flux through this reaction is also changed as there could also be a change in the enzyme concentration, or there could even be altered allosteric regulation of the enzyme, thus keeping the flux unchanged. Thus, our assumption may result in identification of some false positives, but still the analysis would clearly lead to identification of reactions around which there is at least one level of regulation (and possibly several levels of regulation), and we will therefore refer to these reactions as being metabolically regulated. For all the reactions that are not identified as reporter reactions, we cannot infer anything about whether the flux has changed, but still we can deduce from the transcription data whether there has occurred regulation at the hierarchical level, and even though this does not necessarily mean hierarchical regulation of the flux, we will refer to these reactions as being hierarchically regulated.
This deduction can still be informative as indicator of the logic of transcriptional regulatory machinery governing gene expression. For cases where there was a significant change at the transcriptional level for an identified reporter reaction, we considered this to be a situation where there was mixed regulation.

The metabolic network includes several enzymes (hence reactions) governed by multiple genes. Thus, in order to infer about the significance of change in expression levels for the reactions, we summed the transcript levels for all genes coding for the same reaction before applying the statistical test. The $P$-values of transcripts were then calculated by using a $t$-test with unequal variance, and further converted into $Z$-scores to enable a comparison with the $Z$-scores of reactions based on metabolome data.

Using this approach, we grouped all the reactions of the metabolic network into whether they were metabolically or hierarchically regulated (or a combination or not regulated at all) for the VHG data set. To score the magnitude of the regulation at the hierarchical and metabolic levels, we used the corresponding $Z$-scores. The qualitative evaluation of $Z$-scores emerging from the transcriptome and the metabolome data enabled us to get an indication of regulation within the metabolic network (see Supplementary Figure 2 and Supplementary Table 3). The cases where only the transcript $Z$-score is significantly changed can be scored as points with possible hierarchical regulation, whereas the opposite case where only the metabolite-based $Z$-score has significantly changed implies metabolic regulation of the corresponding reaction (Rossel et al., 2004). When both $Z$-scores are significant, there is regulation shared at both levels, and when none of the $Z$-scores are significant, it is not possible to infer about at which level there is regulation.

Of the 121 reactions in the model having corresponding genes associated with them, the number of reactions predicted to be regulated hierarchically, metabolically and at both levels were 56, 7 and 14, respectively for the media perturbation with the laboratory strain, and 31, 14 and 5 for the same perturbation with the industrial strain (Figure 3 and Supplementary Table 3). For the laboratory strain, 44 reactions were found to be relatively irresponsive to the perturbation. On the other hand, the number of potentially unregulated reactions was much higher (71) for the industrial strain. One explanation for the observed predominance of transcriptional regulation could be the fact that the strains protect themselves against the applied perturbation by mainly changing their gene expression to minimize the changes in the metabolome, an observation also encountered in plants (Hirai et al., 2004). Figure 3 and Supplementary Table 3 suggest that metabolic regulation is

![Figure 3](Image 346x99 to 401x694)
mainly predominant for secretion reactions and amino-acid pathways with or without simultaneous hierarchical regulation, the sole exceptions being proline and methionine/cysteine pathways. It is logical to identify the latter as subjected to different regulation, as they are involved in pathways with sulfur assimilation and there were no direct perturbation on sulfur utilization in the experimental study. The type of regulation for a number of reactions differs between the two strains, which supports the finding that gene expression pattern can vary within different S. cerevisiae strains (Ferea et al., 1999; Brem et al., 2002; Townsend et al., 2003; Jansen et al., 2005). Ferea et al (1999) have reported altered expression levels of genes involved in metabolite transport for strains obtained by adaptive evolution in glucose-limited cultures. This observation presents an interesting analogy to our analysis, as the industrial strain is also likely to be a result of adaptive evolution. Similarly, different wild-type strains were found to have widespread variations in expression of genes involved in amino-acid metabolism (Townsend et al., 2003). In order to further validate that the metabolism is different in the industrial and laboratory strains, we performed principal component analysis of the metabolome data for the VHG medium data set (Supplementary Figure 3). This shows a clear distinction of the strains, indicating that the strains behave remarkably different at the level of metabolome. Our analysis systematically combines the transcriptome and metabolome and deduces the underlying regulation causing these differences in metabolism. Notably, following a change to a high-gravity fermentation medium, transcriptional regulation of metabolism is much more predominant in the laboratory strain as compared to the industrial strain, whereas the number of reporter reactions between two strains is around the same with a 70% overlap (Table II). This strongly suggests that although the industrial strain has a better adaptation of its transcriptional program for high-gravity media, there is still a metabolic regulation pattern that is similar to that of the laboratory strain. The difference in strains in terms of their response to the same perturbation is, again, very visible in the secretion reactions where laboratory strain attempts to regulate them also at the transcriptional level, whereas industrial strain relies predominantly on metabolic control (Figure 3 and Supplementary Table 3). The lesser degree of transcriptional regulation in the industrial strain could benefit the cells by reducing the investment of resources in transcriptional regulatory machinery.

Conclusions

In the present study, an integrative algorithm based on metabolome data was introduced for the identification of reporter reactions, defined as the reactions that are responding to a genetic or environmental perturbation through a coordinated variation in the levels of surrounding metabolites. We demonstrate that the algorithm functions, even with a small number of measured metabolites (84), which is a typical situation for several currently used technologies. Moreover, the method developed is suitable for mapping the entire alterations associated with a specific perturbation, depending on the advances in analytical detection techniques enabling the measurement of a larger number of metabolites.

Furthermore, when integrated with transcriptome data, our approach can be used to infer information about whether a reaction is metabolically or hierarchically regulated. Our analysis can therefore be regarded as a genome-scale approach towards the integration of different types of omics data by using metabolic networks as a scaffold in order to understand the architecture of metabolic regulatory circuits. Furthermore, our model-driven analysis is flexible and will further allow integration of other types of omics data, such as proteomics, and this will further refine the method presented herein to account for the genome-scale alterations in response to genetic as well as environmental perturbations, and hence allow genome-scale identification of regulation in the metabolism.

Materials and methods

Graph representation

In the present study, the metabolic network ENZSUB-3 was represented as a bipartite undirected graph to identify reporter reactions. Reactions and metabolites were both taken as nodes, and the edges denoted the interactions between them (Patil and Nielsen, 2005). Hence, the graph consisted of 317 nodes.

Different genetic and environmental perturbations associated with the two data sets (Devantier et al., 2005a; Villas-Bôas et al., 2005a) were analyzed. The graph representation was used to identify ‘reporter reactions’ for these perturbations. The algorithm used in the simulations is a modification of the algorithm recently developed by Patil and Nielsen (2005), which was based on the analysis of transcriptome data to identify so-called reporter metabolites, the spots in the metabolism with substantial transcriptional regulation. The modified algorithm herein has the capability of identifying reporter reactions, the putative key points in the metabolism in terms of metabolic regulation (Figure 1).

Significance test

The significance of change for the experimental metabolite levels between any two conditions was determined by comparing the levels with the aid of a statistical test, thereby quantifying the effect of the associated perturbation. For each of the perturbations, the statistical test was applied to the experimental data following the normalization process described by Villas-Bôas et al. (2005a). Briefly, the normalization process is such that the within-group variances among replicates are reduced and between-group variances are maximized. The Mann–Whitney rank-sum U-test is a nonparametric statistical test, which has no a priori assumption about the distribution type of the data. It was preferred over the standard t-test, as the distribution of levels of some of the metabolites among the replicates, especially NAD+ and NADPH, was found to be skewed rather than normal distributed. The Student’s t-test assumes normal distribution of the data and compares the mean values, whereas the U-test compares medians rather than means. Furthermore, median is a better measure for skewed distributions as it is less sensitive to the extreme scores that can be encountered in the replicates.

Strategy for the lack of data

As the utilized reporter reaction algorithm depends on the scoring of reactions based on the P-values of involved metabolites, the lack of P-values for the 94 metabolites that remain unmeasured in the final ENZSUB-3 model must be handled. Random assignment from GC–MS spectra contain a large number of unknown peaks due to unmeasured metabolites. All the peaks in GC–MS spectra were deconvoluted for each replicate. The output was normalized by using a Python code, which minimizes the sample variability within the classes (Villas-Bôas et al., 2005a). Afterwards, the peaks in the spectra
within a selected time interval (0.15 min) were binned to account for the fluctuations in the retention times using a MATLAB algorithm. This has resulted in the overall detection of 236 unknown peaks for the first data set (Villas-Bôas et al., 2005a), with 116, 178 and 201 non-zero peak comparisons for genetic perturbations under aerobic and anaerobic conditions and environmental perturbations respectively, and 240 unknown peaks for the second data set (Devantier et al., 2005a) with 129 and 174 non-zero peak comparisons for the environmental perturbation of laboratory and industrial strains, respectively. The significance of change for these unknown peaks was quantified for each perturbation by means of P-values using the U-test. These P-values were randomly assigned to the unmeasured metabolites.

**Report reaction analysis**

Resultant P-values were converted to Z-scores using an inverse normal cumulative distribution function for further analysis. Each reaction in the constructed graph was scored by calculating the score of the sub-network formed by its k neighboring metabolites, and z-values of the metabolites were used in the scoring:

\[
Z_{\text{reaction}} = \frac{1}{\sqrt{k}} \sum Z_{\text{metabolite, } k}
\]

Z-score for each reaction was then corrected for background distribution using the mean (\(\mu_k\)) and standard deviation (\(\sigma_k\)) of Z-scores of metabolite groups of the same size, obtained by random sampling from the same metabolic network

\[
Z_{\text{corrected reaction}} = Z_{\text{reaction}} - \frac{\mu_k}{\sigma_k}
\]

In order to minimize the sensitivity of reporter reactions to the randomly selected P-values for the non-measured metabolites as mentioned above, the reporter reaction algorithm was executed 1000 times by repeating the random assignment in each case. This repetition eliminated the effect of the P-values of the assigned peaks on results. For each reaction, the Z-scores in each repetition were averaged to get a final Z-score. Those reactions with the highest Z-scores (typically \(Z > 1.28\), corresponding to \(P < 0.10\)) can be defined as reporter reactions for a system with complete metabolome data. As available experimental data were not complete, the calculated Z-scores were used for deducing the relative significance of the reactions in the analyzed perturbations. In other words, we mainly focus on comparative analysis of reactions among the studied perturbations, as revealed by Figure 2, rather than comparing a reaction to another based on its Z-score. The underlying reason is to avoid potentially incorrect conclusions due to the unmeasured metabolites, which have randomly assigned P-values. Additionally, the analyzed reactions have a high percentage of measured metabolite content, as indicated in Tables I and II. In the case of low coverage of measured metabolite content, this method should be followed with caution as the resultant Z-scores of reactions will become insignificant, and such reactions will not be picked up as reporters. However, in future, when analytical methods have been further improved, it is likely that more metabolites can be measured, and one will overcome this shortcoming and our approach may then be used to infer more soundly about the level of regulation at different parts of large metabolic networks. Based on the features of our algorithm, we suggest certain guidelines for the metabolome measurements in order to effectively exploit our approach: (i) measurement of metabolites that participate in many reactions (hubs in the metabolic network) will increase the performance of the algorithm and (ii) measurement of metabolites that participate in certain closely related pathways (metabolites that are closely placed in the network) will increase the confidence in the obtained Z-scores for reactions in these pathways (see Supplementary note 1 for further discussion).

**Computational tools**

METATOOL 4.3 (Pfeiffer et al., 1999) was used for the identification of enzyme subsets in the UNCOMP model. The codes written in MATLAB 7.0 (MathWorks Inc.) were utilized for the model preprocessing summarized above and to call the algorithm written in C ++ for reporter reaction identification. FBA was performed using in-house software BioOpt employing LINDO API for linear optimization. Deconvolution of peaks in GC–MS spectra for the identification of metabolites based on a metabolite library and for the random peak assignment was achieved using AMDIS software (Stein, 1999), and the peak normalization software was kindly provided by JF Moxley.

**Supplementary information**

Supplementary information is available at the Molecular Systems Biology website (www.nature.com/msb).

**Acknowledgements**

Isabel Rocha (University of Minho, Portugal) is gratefully acknowledged for fruitful suggestions. We thank JF Moxley (MIT) for the metabolome normalization software. S Villas-Bôas and R Devantier are acknowledged for providing detailed information on the experimental data. We thank the anonymous reviewers for several constructive suggestions. The research was partly supported by the Bogazici University Research Fund through project 04HA502, and by DPT through 03K120250. The doctoral fellowship for Tunahan Çakır is sponsored by BAYG-TÜBİTAK within the framework of the integrated PhD program.
