ABSTRACT

We employ isolated N-body simulations to study the response of self-interacting dark matter (SIDM) halos in the presence of the baryonic potentials. Dark matter self-interactions lead to kinematic thermalization in the inner halo, resulting in a tight correlation between the dark matter and baryon distributions. A deep baryonic potential shortens the phase of SIDM core expansion and triggers core contraction. This effect can be further enhanced by a large self-scattering cross section. We find the final SIDM density profile is sensitive to the baryonic concentration and the strength of dark matter self-interactions. Assuming a spherical initial halo, we also study evolution of the SIDM halo shape together with the density profile. The halo shape at later epochs deviates from spherical symmetry due to the influence of the non-spherical disk potential, and its significance depends on the baryonic contribution to the total gravitational potential, relative to the dark matter one. In addition, we construct a multi-component model for the Milky Way, including an SIDM halo, a stellar disk and a bulge, and show it is consistent with observations from stellar kinematics and streams.

1 INTRODUCTION

The Λ cold dark matter (ΛCDM) model, where DM is assumed to be collisionless, is the leading theory for the growth of structure and formation of galaxies in our Universe. It fits the spectrum of matter fluctuations in the early universe with extraordinary precision (Planck Collaboration et al. 2014) and explains many important aspects of galaxy formation and evolution (Springel et al. 2006; Trujillo-Gomez et al. 2011; Frenk & White 2012; Vogelsberger et al. 2014a; Vogelsberger et al. 2014c). However, the success of ΛCDM does not preclude the possibility that DM may have strong self-interactions. When DM particles have a scattering cross section per unit mass, $\sigma_s/m_\chi \sim 1$ cm$^2$/g, DM collisions occur multiple times in the inner halo over the cosmological timescale and make distinct departures from the CDM predictions, while the outer halo remains collisionless, retaining the large-scale predictions of CDM (Spergel & Steinhardt 2000; Yoshida et al. 2000; Davé et al. 2001; Colín et al. 2002; Vogelsberger et al. 2012; Rocha et al. 2013). In fact, SIDM has been motivated to address outstanding discrepancies between observations on galactic scales and CDM predictions, see Bullock & Boylan-Kolchin (2017) for a recent review on the CDM challenges and Tulin & Yu (2017) on their solutions within SIDM. In particular, it has been shown that the diverse shapes of galactic rotation curves (Oman et al. 2015; Kuzio de Naray et al. 2010) can be explained naturally in the SIDM model (Kamada et al. 2017; Creasey et al. 2017), while being consistent with observations in galaxy clusters (Kaplinghat et al. 2016).

DM self-interactions kinematically thermalize the inner halo and lead to distinct features in the halo properties. For dwarf galaxies, where DM dominates over all radii, SIDM thermalization leads to a large density core, and the stellar distribution is more extended in SIDM than CDM and there is tight correlation between the DM core size and the stellar one (Vogelsberger et al. 2014b). While for baryon-dominated systems, the thermalization can significantly increase the central SIDM density and the inner halo shape follows the baryon distribution due to the influence of the baryonic potential (Kaplinghat et al. 2014), a radical deviation from SIDM-only simulations. Moreover, Kaplinghat et al. (2014) argued that once the inner halo reaches equilibrium, the inner SIDM profile can be
modeled as an isothermal distribution that is sensitive to the final baryonic potential, but not the formation history. This has motivated a number of isolated simulations to test the response of the SIDM halo to the baryonic potential (Elbert et al. 2016; Creasey et al. 2017), where they assumed a CDM halo and a stellar potential as the initial condition. Recently, Robertson et al. (2017) performed cosmo-hydrodynamical SIDM simulations of galaxy clusters and explicitly confirmed this expectation. In addition, although in the presence of strong baryonic feedback both CDM and SIDM could lead to similar density profiles (Fry et al. 2015), the internal structure of the SIDM halo is more robust to the inclusion of baryonic feedback, compared to its CDM counterpart, due to the rapid energy redistribution caused by the DM collisions (Robles et al. 2017).

In this paper, we utilize isolated simulations to study the response of the SIDM halo in the presence of the baryonic potential for Milky Way (MW)-sized galaxies, where the baryonic contribution to the potential is important. Our goal is to understand the interplay between the DM self-scattering strength and the baryonic concentration in shaping the SIDM distribution, and the significance of the potential in altering evolution history of the SIDM halo. In the first two sets of simulations, we vary both the baryonic concentration and \( \sigma_s/m_s \) in the range of 0.5–5 cm\(^2\)/g, and study the variation of the SIDM predictions in the density profile and shape as a function of the cross section. In the presence of baryons, the central density of an SIDM halo no longer decreases monotonically with increasing \( \sigma_s/m_s \), as expected in the SIDM-only case for \( \sigma_s/m_s \) we take. Accordingly, the SIDM halo shape varies with \( \sigma_s/m_s \) even for the same baryonic potential. Our results indicate that inferring \( \sigma_s/m_s \) from stellar kinematics of luminous galaxies, where the baryons dominate the potential, could be challenging.

In our third set of simulations, we construct a realistic MW mass model, including an SIDM halo, a stellar bulge and disk. We fix \( \sigma_s/m_s = 1 \) cm\(^2\)/g and carefully adjust the model parameters to reproduce the mass model inferred from the stellar kinematics. We then make a detailed comparison between the halo shape predicted in our model and those inferred from observations.

The structure of this paper is as follows. In Sec. 2, we discuss the numerical details of our simulations and the methodology used to quantify the halo shapes. In Sec. 3, we use our code to explore the evolution of a MW-sized halo with a stellar disk and measure the effect of the radial length scale of the disk. In Sec. 4, we compare our predictions for an SIDM MW halo against those from CDM simulations and those inferred from observations of stellar streams. We conclude and summarize our results in Sec. 5.

2 SIMULATIONS AND HALO SHAPE ALGORITHMS

2.1 Numerical Simulations

We carry out N-body simulations using the code AREPO (Springel 2010). Gravity modules in Arepo are a modified version of GADGET-2 and GADGET-3 (Springel 2005). We use the algorithm developed in Vogelsberger et al. (2012, 2016) to model DM self-interactions. This is a Monte Carlo-based method, where at each time step a particle may pairwise scatter with any of its nearest neighbors. We assume a velocity-independent constant cross section in our simulations. This is a good approximation, since the observationally self-scattering cross section varies mildly across galactic scales (Kaplinghat et al. 2016) and we mainly focus on isolated simulations for a given halo mass. We evolve our simulations for 10 Gyr, slightly shorter than Hubble time scale \( (H_0^{-1} \approx 13.96 \text{ Gyr}) \) in order to account for the assembly of the primordial galactic halo.

Following Creasey et al. (2017), we model the baryonic component in our simulations as a static potential. This approach ignores the back-reaction of the halo evolution on the baryons, an effect expected to be sub-dominant, since we are interested in the systems that the final baryonic distribution is known. We consider two models for the baryonic potential. One is the Miyamoto-Nagai (MN) disk (Miyamoto & Nagai 1975),

\[
\Phi_{\text{MN}}(R, z) = \frac{-G M_d}{\sqrt{R^2 + (R_d + \sqrt{d^2 + z^2})^2}},
\]

where \( M_d \) is the disk mass, \( R_d \) the disk scale length and \( z_d \) the disk scale height. The implementation of the MN disk in AREPO is as described in Creasey et al. (2017). We also consider a Hernquist bulge potential (Hernquist 1990)

\[
\Phi_{\text{Hernquist}} = -\frac{G M_b}{r + r_h},
\]

where \( M_b \) is the bulge mass and \( r_h \) is the scale length.

We run three sets of simulations, varying the baryonic component and the strength of the cross section. In the first two sets, we only include the MN disk \( (M_d = 6.4 \times 10^{10} M_\odot) \) with two disk scale lengths, \( R_d = 3 \) kpc (compact disk) and \( R_d = 6 \) kpc (extended disk). In both cases, we fix \( z_d = 0.3 R_d \). The DM self-scattering cross section is chosen to be \( \sigma_s/m_s = 0, 0.5, 1, 3, \) and 5 cm\(^2\)/g, i.e., 10 simulations in total. For the initial halo component, we assume a spherical NFW profile Navarro et al. (1997), and take the halo parameters as \( r_s = 37.03 \) kpc and \( c_s = 2.95 \times 10^5 M_\odot/kpc^3 \). The mass ratio of the disk to the halo is motivated by the baryonic Tully-Fisher relation (Lelli et al. 2016). We use the publicly available code SPHERIC, introduced in Garrison-Kimmel et al. (2013), to generate the initial conditions. It truncates the outer halo profile exponentially at \( r_{\text{cut}} \) to avoid mass divergence. We take \( r_{\text{cut}} \approx 250 \) kpc, close to the virial radius of our initial CDM halo. We fix the gravitational softening length to be \( \epsilon = 125 \) pc and the mass resolution \( m_p = 1.32 \times 10^8 M_\odot \). We include 2 million mass particles in our simulations, necessary for resolving the innermost regions, resulting in a halo mass of \( 2.64 \times 10^{12} M_\odot \).

For the third set, we include both an MN disk and a Hernquist bulge to model the baryon distribution in the MW. The disk parameters are \( M_d = 6.98 \times 10^{10} M_\odot, R_d = 3.38 \) kpc and \( z_d = 0.2 R_d \) for the disk. The bulge ones are \( M_b = 1.05 \times 10^{10} M_\odot \) and \( r_h = 0.46 \) kpc. The initial halo parameters are \( r_s = 42.18 \) kpc and \( c_s = 1.39 \times 10^5 M_\odot/kpc^3 \). We have chosen these parameters to reproduce the MW mass model presented in McMillan (2011) (hereafter McM11), see Sec. 4 for details. The baryon-model parameters used in our simulations are summarized in Table 1. We choose \( r_{\text{cut}} = 100 \) kpc, \( \epsilon = 125 \) pc and \( m_p = 5.76 \times 10^4 M_\odot \). We simulate 2 million mass particles and the total halo mass is \( 1.15 \times 10^{12} M_\odot \).

Additionally, we have run cosmological zoom-in SIDM simulations for 5 MW-mass Aquarius halos (Springel et al. 2008) with...
The elliptical radius found from the previous inertia tensor. We have $q = \sqrt{\lambda_2/\lambda_3}$ and $s = \sqrt{\lambda_1/\lambda_3}$. In the initial iteration, the ellipsoid is set to a sphere, i.e. $q = s = 1$. This process is continued until some convergence criteria, which we take it to be $10^{-6}$, on the difference between successive iterations, is satisfied. We note that if the number of DM particles in an ellipsoid is too small, typically less than 1000, the result from this method is not accurate (see Appendix A).

Fig. 1 shows a comparison between isodensity contours and ellipsoids for an example, where $R_d = 6$ kpc and $\sigma_s/m_s = 1$ cm$^2$/g. We see the overall agreement between the two methods is excellent.

3 SIDM HALO PROPERTIES WITH A STELLAR DISK

3.1 Density profiles

Fig. 2 shows the DM density (top) and velocity dispersion (bottom) profiles for $R_d = 3$ kpc (left) and 6 kpc (right). The solid curves are from our simulations for different values of $\sigma_s/m_s$ in the presence of the stellar disk. For comparison, we also plot the SIDM density profiles (dashed) without the disk potential, calculated with the analytical method in Kaplinghat et al. (2014, 2016).

In both cases, the presence of a baryonic potential increases the SIDM density profile and reduces the core size, and the effect is more significant if the baryonic concentration is higher. For $R_d = 3$ kpc, a larger cross section leads to a higher DM density (0.5–5 cm$^2$/g), opposite to the case without baryons. For the extended disk with $R_d = 6$ kpc, the SIDM density profiles are almost identical, even though the $\sigma_s/m_s$ value changes by a factor of 10. A deep baryonic potential also increases the DM velocity dispersion in the inner halo, as shown in the bottom panels. In the case of compact disk, it is evident that the SIDM halos are close to the threshold of mild core collapse, as the velocity dispersion profiles start to develop a negative gradient. The significance is continuously enhanced when $\sigma_s/m_s$ changes from 0.5 to 5 cm$^2$/g. We have checked simulation results using the analytical method, where we assume a thin disk model and use the numerical templates developed in Kamada et al. (2017). They agree within 5–20% in the central DM density and velocity dispersion.

The SIDM halo has a distinct evolution history. It first undergoes a core expansion phase, during which the DM collisions transport heat towards the inner region and a central density core forms. Since a self-gravitating system has a negative heat capacity, the core will eventually contract and collapse to a singular state (Balberg et al. 2002). In cosmological SIDM-only simulations, mild core collapse is observed within 10 Gyr when $\sigma_s/m_s \gtrsim 10$ cm$^2$/g (Vogelsberger et al. 2012; Elbert et al. 2015). We have also checked that for isolated SIDM-only ones with an NFW profile as the initial condition, the core contraction does not occur within 10 Gyr for $\sigma_s/m_s = 0.5–5$ cm$^2$/g, consistent with the results in Koda & Shapiro (2011). However, the SIDM thermalization with a deep baryonic potential can speed up this process, as shown in our simulations (see also Elbert et al. 2016).

We see that the presence of the stellar potential breaks the monotonic relation between the value of $\sigma_s/m_s$ and the central SIDM density. The effect depends on the baryonic concentration and the size of the self-scattering cross section. Our results indicate that it could be challenging to extract the $\sigma_s/m_s$ information from stellar kinematics of galaxies dominated by baryons.
Figure 2. Simulated DM density (top, solid) and velocity dispersion (bottom) profiles for $\sigma_x/m_x = 0$ (gray), 0.5 (red), 1 (blue), 3 (green), and 5 cm$^2$/g (magenta), in the presence of compact (left) and extended (right) disks. On the top panels, we also plot the corresponding NFW initial condition and the SIDM density profiles derived from the analytical method without including the stellar potential (dashed, the same color scheme as the solid ones), together with the disk mass profile (dash dotted).

Figure 3. Projected SIDM distributions in edge-on views for compact (left) and extended (right) disks with different SIDM cross sections as given in the legend.
In Fig. 3, we show the SIDM halo surface densities for the central DM velocity dispersion for $\sigma_R$.

Halo shapes denotes the scale radius of the stellar disk. We calculate the numerical errors using the bootstrapping method.

It is also evident that the simulated halos are not spherically symmetric, as expected from the density profiles shown in Fig. 2. It is also evident that the simulated halos are not spherically symmetric, although their initial conditions are exactly spherical.

Fig. 4 shows the ratio of minor-to-major axes vs. elliptical radius $\sqrt{R^2 + (z/s)^2}$ for $R_d = 3$ kpc and $R_d = 6$ kpc with different cross sections (solid). In all cases, the $c/a$ value deviates from 1 and decreases towards the center ($b/a$ remains close to 1). However, the SIDM halos are more responsive to the presence of the baryonic disk than their collisionless counterpart, and their shapes are more aligned with the axisymmetric disk potential (dashed). Interestingly, for the compact case, $c/a$ increases when the cross section increases from 0.5 to 5 cm$^2$/g and the inner halo becomes rounder mildly. We can see a similar trend in the case of $R_d = 6$ kpc, although the errors in measuring $c/a$, calculated using bootstrap method, for $r < R_d$ are large due to the lack of enough DM particles in the central region of the halos.

The behavior in Fig. 4 can be understood as follows. Since the DM self-interactions thermalize the inner halo, the DM density can increase when $\sigma_x/m_x$ increases from 0.5 to 5 cm$^2$/g, as well as the DM dispersion (very mildly), as shown in Fig. 2 (left). Accordingly, the baryonic potential becomes less dominant and the inner halo becomes more spherical. Note in the compact-disk case the simulated $c/a$ profile for $\sigma_x/m_x = 0.5$ cm$^2$/g agrees well with the isothermal profile due to the baryonic potential, because of the strong dominance of the disk in the inner regions. In addition, for $\sigma_x/m_x = 5$ cm$^2$/g (compact), both the inner DM density and velocity dispersion are higher, compared to the CDM case, but the SIDM halo is more aspherical and aligned with the disk than the CDM one. In the extended-disk case, the halo $c/a$ profiles also follow the disk one, but not as close as the compact case, since the disk does not dominate the potential at all radii, as shown in Fig. 2 (right).

3.2 Halo shapes

In Fig. 3, we show the SIDM halo surface densities for $R_d = 3$ kpc (left) and $R_d = 6$ kpc (right). The density contrast for the compact case is higher for different cross sections, compared to the extended one, as expected from the density profiles shown in Fig. 2. It is well evident that the simulated halos are not spherically symmetric, although their initial conditions are exactly spherical.

We also plot $c/a$ for the isothermal profile when the disk dominates the gravitational potential (dashed), $\rho_{DM} \propto \exp[-\Phi_{MN}(R,z)/\sigma_c^2]$, where we take the central DM velocity dispersion for $\sigma_x/m_x = 0.5$ cm$^2$/g, i.e., $\sigma_v \approx 168$ (compact) and 150 km/s (extended), as shown in Fig. 2 (bottom). The arrow denotes the scale radius of the stellar disk. We calculate the numerical errors using the bootstrapping method.

3.3 Evolution history

In this section, we take a closer look at the evolution of the SIDM halo and explicitly show that the presence of the baryonic potential does speed up core contraction and shorten the expansion phase.

Fig. 5 shows the density and $c/a$ profiles at different epochs for three examples: the lowest (top) and highest (middle) cross sections in the simulations with the extended disk, and the highest cross section for the compact disk case (bottom). For $R_d = 6$ kpc and $\sigma_x/m_x = 0.5$ cm$^2$/g, the simulated halo is on the core expansion phase over the 10 Gyr span of the simulation. In this case both central DM density and the $c/a$ ratio decrease continuously. When we increase the cross section to 5 cm$^2$/g (middle), the duration of the core expansion phase becomes much shorter. After about 1 Gyr, the halo enters the core contraction phase and the central DM density increases, as well as the ratio of minor-to-major axes. A more compact stellar disk can change the halo evolution even more dramatically, as shown in the bottom panel. The simulated halo almost never gets into the expansion phase and the central density and $c/a$ in the regions increases over time monotonically. In this...
Figure 5. Time evolution of the DM density (left) and the halo shape (right) profiles for three representative examples, including simulations with the extended disk for $\sigma_x/m_x = 0.5 \text{ cm}^2/\text{g}$ (top) and $5 \text{ cm}^2/\text{g}$ (middle), and the compact one for $\sigma_x/m_x = 5 \text{ cm}^2/\text{g}$ (bottom). Different colors denote different evolution epochs, and both left and right panels have the same color scheme.
DM density (M⊙/kpc3)

We conclude that the evolution history of the SIDM halo is sensitive to the presence of the baryonic potential. The final halo properties, such as the density profile and the ellipticity, depend on the baryonic concentration and the strength of DM self-interactions.

4 IMPLICATIONS FOR THE SHAPE OF THE MILKY WAY HALO

The effect of baryons on the SIDM halo can potentially be tested with observations of the MW. Here, we construct a model for the MW potential consisting of an SIDM halo, a baryonic bulge and disk. The DM halo is chosen initially as a spherical NFW profile with \( r_s = 42.18 \) kpc and \( \rho_s = 1.39 \times 10^6 M_\odot/kpc^3 \). We model the disk following an MN potential as in Eq. 1, with disk length scale and mass specified in Table 1 and bulge following a spherical Hernquist profile. We take the cross section as \( \sigma_s/m_s = 1 \) cm²/g.

Top panel of Fig. 6 shows the DM density profiles for our SIDM halo (blue), the initial NFW model (gray), and the halo model in McM11 (black). Our MW model reproduces well the estimates for the local DM density near the solar neighborhood from Bovy & Tremaine (2012) (red). Note the initial halo concentration is about 1.5 \( \sigma \) lower than the average for the MW mass object according to Dutton & Macciò (2014) and also lower than that in McM11. This is a necessary choice to be consistent with observations, since SIDM thermalization significantly increases the DM density in the inner regions due to the presence of the baryonic potential. Although the inner density profile of the SIDM halo deviates from the McM11 one, our MW mass model produces a circular velocity profile, consistent with the one in McM11 within 10% uncertainties, as shown in Fig. 6 (bottom).

Fig. 7 shows the ratio of minor-to-major axes as a function of the elliptical radius, predicted in our SIDM MW halo model with \( \sigma_x/m_x = 1 \) cm²/g (blue solid). Since we assume a spherical NFW initial halo, the deviation from \( c/a = 1 \) is caused by the disk potential. We see the disk induces a mild asphericity in the inner regions of the halo, \( c/a \sim 0.7–0.8 \), in good agreement with the result based on the analytical model in Kaplinghat et al. (2014), where the spherical boundary condition is imposed at 10 kpc. Our simulations also show the effect is quite extended, with \( c/a \) converging back to unity only at the distance \( 30 \) kpc. We also present cosmological SIDM-only simulations of 5 Aquarius halos with \( \sigma_x/m_x = 1 \) cm²/g. Our results are in agreement with the previous ones (Peter et al. 2013; Brinckmann et al. 2018). For the roundest halos (Aq-A and Aq-C), \( c/a \gtrsim 0.85 \) for \( r \lesssim 30 \) kpc, lending support to our assumption of an initially spherical NFW halo. Since the DM self-scattering rate increases by a factor of 100 from 30 kpc to inner few kpc, as indicated by the DM density pro-
file shown in Fig. 6 (top), we expect the spherical assumption is well-justified in the inner halo.

The MW halo shape has been inferred from observations of stellar streams such as GD-1 and Pal 5 (e.g., Koposov et al. 2010; Bowden et al. 2015; Pearson et al. 2015; Küpper et al. 2015; Bovy et al. 2016). In Fig. 7, we show the results presented in Bovy et al. (2016) for GD-1, Pal 5 and the combined one, where an axisymmetric NFW density profile with $b/a = 1$ was used to model the DM distribution in the MW. We see that the phase-space tracks of the streams are consistent with a spherical DM halo in the MW at intermediate radii, $r \sim 20 \text{ kpc}$, which indicates any asphericity either intrinsic to the DM distribution or induced by the disk should be at most on that scale in order to accommodate the measurements. Our model predicts $c/a \sim 0.85$ at $r \approx 20 \text{ kpc}$, consistent with the combined constraint on $c/a$ within $\sim 1.5\sigma$. Note that our scale height in the MN disk is $z_h \approx 0.68 \text{ kpc}$, higher than the best-fit value $\approx 0.3 \text{ kpc}$ in Bovy et al. (2016). We have estimated that taking their $z_h$ value would reduce $c/a$ by 5% at most in the inner regions and the difference becomes negligible around 10 kpc. In addition, in our MW model, the total halo mass within 20 kpc is $1.28 \times 10^{11} M_{\odot}$, consistent with $M_{\text{halo}}(r < 20 \text{ kpc}) = 1.1 \pm 0.1 \times 10^{11} M_{\odot}$ measured in Bovy et al. (2016), although our initial NFW halo has lower concentration, compared to theirs ($r_s = 18.0 \pm 7.5 \text{ kpc}$). It would be interesting to analyze the stream data with the SIDM halo model.

For comparison, we also plot cosmological CDM-only (gray) and hydrodynamical (red) simulations from the NIHAO project (Butsky et al. 2016). As is well-known, CDM halos from cosmological simulations are strongly triaxial (Frenk et al. 1988; Jing & Suto 2002; Hayashi et al. 2007; Kuhlen et al. 2007; VeraCiro et al. 2011; Diemand & Moore 2011). Taken at face value, CDM predictions (gray) could look at odds with the observations. However, baryons can make the CDM halo shapes more spherical (red) (see also, Dubinski 1994; Debattista et al. 2008; Kazantzidis et al. 2010; Abadi et al. 2010; Tissera et al. 2010), an effect partially attributed to the change of orbits from boxy to tube or rounder loop as a result of the central concentration of baryons (Debattista et al. 2008). In the NIHAO simulations, the mean value of $c/a$ is 0.7 for the CDM halos after including baryons, and it can reaches 0.8 at the 1$\sigma$ level of the scatter, consistent with the observations reasonably well.

Although the sphericity created by the baryons helps CDM to accommodate more easily the observational constraints, the trend with radius could be different in the two models. It seems that CDM halos plus baryons become more spherical at all radii, whereas the effects explored here in SIDM plus baryons would anticipate a flattening of the shapes towards the inner regions that follows that of the disk. Such premise, of course, ignores any effect of feedback or cosmological assembly, which may cause deviations of the system from equilibrium. Therefore, the exciting premise of using halo shape profiles to differentiate DM candidates awaits confirmation from cosmological hydrodynamical SIDM simulations. We hope such experiments will become available in the near future.

5 CONCLUSIONS

We use isolated N-body simulations of DM halos with static disk potentials to explore the gravitational effect of baryons on SIDM halos. We model the disk as a Miyamoto-Nagai potential embedded within an initially NFW halo with mass $\sim 10^{12} M_{\odot}$. We consider different self-scattering cross sections, $\sigma_x/m_x = 0.5, 1, 3,$ and $5 \text{ cm}^2/\text{g}$ besides the special case, $\sigma_x/m_x = 0 \text{ cm}^2/\text{g}$. In addition, we vary the radial length scale of the disk, $R_d$, to study in detail how the DM halo responds to the baryons as a function of how relevant their contribution is to the total potential at a given radius.

In the absence of baryons, SIDM halos develop a central flat core with its density and size that depend mostly on the self-scattering cross section. We confirm that the inclusion of a disk potential can change this behavior due to SIDM thermalization with the potential, resulting in a higher core density and a smaller core than expected without the disk, a crucial effect in solving the diversity problem in SIDM (Kamada et al. 2017; Creasey et al. 2017).

We highlight two phases of evolution during our numerical experiments: a first stage of core expansion, during which the density core gets established due to the turn-on of the self-interactions, and a second stage of core contraction due to the gravitational effects of the baryons. The timescale for these two phases of evolution is a function of both, the cross section and the relative importance of the baryons inside the core. Higher cross sections and more compact baryonic disks (encoded in a smaller length scale) speed up the transition between the two phases and make the timescale of core expansion shorter.

We have also studied the role of the disk potential in shaping the SIDM halo. To explore this subtle effect, we assumed an exact spherical initial NFW profile such that any departure from sphericity is due to the influence of the baryonic potential. Compared to the case of $\sigma_x/m_x = 0 \text{ cm}^2/\text{g}$, the SIDM halos are more responsive to the potential due to the thermalization, and their flat flattening is more aligned with the orientation of the disk, consistent with the expectation from the analytical method. Our simulations clearly demonstrate that the induced asphericity is mainly sensitive to the contribution of the disk to the total potential, relative to the DM one. We further confirmed this by checking the evolution history of the SIDM halos. The flattening effect is maximized during the epoch when the core has the lowest density, which coincides with the time when the disk contribution to the total potential is also maximized.

We have constructed a mass model for the MW and explored the shape prediction with observations. The model consists of a stellar disk and a bulge, embedded within a spherical SIDM halo. It reproduces observed stellar kinematics of the Galaxy within the uncertainties and the local DM density reported in the solar neighborhood. We find that the baryons are able to induce a mild flattening ($c/a \sim 0.7–0.8$) in the inner regions but the effect weakens at larger radii. At $r \sim 20 \text{ kpc}$ where observational constraints seem to suggest an almost spherical halo, the effects of the disk are not strong, in agreement with the observations. We propose that the quasi sphericity of the halo at large distance is easier to accommodate in SIDM models than within the strongly triaxial structures predicted by CDM, although considering the effects of baryons might help to reconcile CDM models with observed spherical halos. Furthermore, we argue that a study of halo shapes as a function of radius might be able to help distinguish the nature of DM, although a more stringent comparison to cosmological simulations are needed to confirm this last point. On the observational side, future surveys capable of inferring the shape of the Galactic halo within the inner 20 kpc regions are promising avenues to make progress on establishing the non-canonical nature of DM.

APPENDIX A: CONVERGENCE TEST FOR THE HALO SHAPE ALGORITHM

To evaluate accuracy of the shape measurement, we follow Vera-Ciro et al. (2011) to determine the convergence radius where shape measurements are robust in our simulations. We consider the convergence radius $r_{\text{conv}}$ (Power et al. 2003; Navarro et al. 2010),

$$\kappa(r_{\text{conv}}) \equiv \frac{t_{\text{relax}}}{t_{\text{cir}}(r_{200})} = \sqrt{\frac{200}{8}} \left( \frac{N(r_{\text{conv}})}{N(r_{200})} \right)^{1/2} \ln \left( \frac{\bar{\rho}(r_{\text{conv}})}{\rho_{\text{crit}}} \right)$$

where $t_{\text{relax}}$ is the two-body relaxation time scale due to gravitational encounters, $t_{\text{cir}}$ is the circular orbit timescale at $r_{200}$, $N$ is number of DM particles and $\bar{\rho}$ is the average density inside the convergence radius. We take $\kappa(r_{\text{conv}}) = 7$ as in Vera-Ciro et al. (2011). In addition, we require $\sim 70\%$ of the particles to be inside the virial sphere and at least 2000 DM particles inside of convergence radius.

The first requirement is satisfied if we choose a large cutoff radius in the SPHERIC code, at which the density profile transits from an NFW one to an exponentially decaying one to avoid the divergence of the mass. Then we run three simulations with different values of the DM particle number and the gravitational softening length as a convergence test with details summarized in Table A1. The convergence radius decreases with increasing the number of total DM particles. Thus, to probe the shape of the inner halo, down to few kpc, we need at least 2 million particles in simulations. Fig. A1 shows the $b/a$ (top) and $c/a$ (bottom) profiles for different resolutions, we take a static MN potential as stellar disk similar to Sec. 3, with a MW-sized halo with $M_{200} \approx 2.6 \times 10^{12} M_\odot$. We see that the convergence improves when $N_{\text{tot}}$ increases. We take high-resolution run in the results presented in Sec. 3 and 4.

| Resolution Level | $m_p$ ($M_\odot$) | $N_{\text{tot}}$ | $\epsilon$ (pc) | $r_{\text{conv}}$ (kpc) | $N_{\text{conv}}$ |
|------------------|------------------|-----------------|-----------------|------------------------|-----------------|
| Low              | $2.18 \times 10^8$ | $1.6 \times 10^5$ | 500             | 6.08                   | 1190            |
| Intermediate     | $3.97 \times 10^6$ | $8.8 \times 10^5$ | 250             | 2.99                   | 1813            |
| High             | $1.31 \times 10^6$ | $2 \times 10^6$   | 125             | 2.18                   | 2192            |

Table A1. Summary of simulations for convergence test. $m_p$ is mass of each particle in each simulation, $N_{\text{tot}}$ is total number of particles, $\epsilon$ is gravitational softening length, $r_{\text{conv}}$ is convergence radius, and $N_{\text{conv}}$ is number of particles inside $r_{\text{conv}}$. |
