The direct detection of dark matter constituents, in particular the weakly interacting massive particles (WIMPs), is central to particle physics and cosmology. In this paper we study transitions to the excited states, possible in some nuclei, which have sufficiently low lying excited states. Examples considered previously were the first excited states of $^{127}$I and $^{129}$Xe. We examine here $^{83}$Kr, which offers some kinematical advantages and is a possible target. We estimate appreciable rates for the inelastic scattering mediated by the spin cross section, with an inelastic event rate of $4.4 \times 10^{-4}$ kg$^{-1}$ d$^{-1}$. So, the extra signature of the gamma ray following the de-excitation of these states can, in principle, be exploited experimentally. A brief discussion of the experimental feasibility is given.

I. INTRODUCTION

At present there exists plenty of evidence of the existence of dark matter i) from cosmological observations, the combined MAXIMA-1 [1], BOOMERANG [2], DASI [3], COBE/DMR Cosmic Microwave Background (CMB) observations [4] [5], as well as the recent WMAP [6] and Planck [7] data and ii) the observed rotational curves in the galactic halos, see e.g. the review [8]. It is, however, essential to directly detect such matter in order to unravel the nature of its constituents.

At present there exist many such candidates, called Weakly Interacting Massive Particles (WIMPs), e.g. the LSP (Lightest Supersymmetric Particle) [9–15], technibaryon [16, 17], mirror matter [18, 19], Kaluza-Klein models with universal extra dimensions [20, 21] etc. These models predict an interaction of dark matter with ordinary matter via the exchange of a scalar particle, which leads to a spin independent interaction (SI) or vector boson interaction, which leads to a spin dependent (SD) nucleon cross section. Additional theoretical tools are the structure of the nucleus, see e.g. [22–25], and the nuclear matrix elements [26–30].

In this paper will focus on the spin dependent WIMP nucleus interaction. This cross section can be sizable in a variety of models, including the lightest supersymmetric particle (LSP) [28, 31–33], in the co-annihilation region [34], where the ratio of the SD to to the SI nucleon cross section, depending on tan $\beta$ and the WIMP mass can be large, e.g. $10^3$ in the WIMP mass range 200-500 GeV. Furthermore more recent calculations in the supersymmetric SO(10) model [35], also in the co-annihilation region, predict ratios of the order of 2 $\times$ 10$^3$ for a WIMP mass of about 850 GeV. Models of exotic WIMPs, like Kaluza-Klein models [20, 21] and Majorana particles with spin 3/2 [36], also can lead to large nucleon spin induced cross sections, which satisfy the relic abundance constrain. This interaction is very important because it can lead to inelastic WIMP-nucleus scattering with a non negligible probability, provided that the energy of excited state is sufficiently low, a prospect proposed long time ago [37] and considered in some detail by Ejiri and collaborators [38]. Indeed for a Maxwell-Boltzmann (M-B) velocity distribution the average kinetic energy of the WIMP is:

$$\langle T \rangle \approx 50 \text{ keV} \frac{m_X}{100 \text{ GeV}}$$  \hspace{1cm} (1)

So, for sufficiently heavy WIMPs, the available energy via the high velocity tail of the M-B distribution maybe adequate [39] to allow scattering to low lying excited states of of certain targets, e.g. of $57.7 \text{ keV}$ for the 7/2$^+$ excited state of $^{127}$I, the 39.6 keV for the first excited 3/2$^+$ of $^{129}$Xe, the 35.48 keV for the first excited 3/2$^+$ state of $^{125}$Te and the 9.4 keV for the first excited 7/2$^+$ state of $^{83}$Kr.

In fact we expect that the branching ratio to the excited state will be enhanced in the presence of non zero energy threshold, since only the total rate to the ground state transition will be affected and reduced by the threshold, while this will have a negligible effect on the rate due to the inelastic scattering. The analysis is simplified if, as expected from particle models as well as the structure of the nucleon, the isovector nucleon cross section is dominant.
II. THE SPIN DEPENDENT WIMP-NUCLEUS SCATTERING

The spin dependent WIMP-Nucleus cross section is typically expressed in terms of the WIMP-nucleon cross section, which contains the elementary particle parameters entering the problem at the quark level. From the particle physics point of interaction of WIMPs with ordinary matter is given at the quark level by two amplitudes, one isoscalar $a_0(q)$ and one isovector $a_1(q)$. In going to the nucleon level one must transform these two amplitudes by suitable renormalization factors given in terms of the quantities $\Delta q$ prescribed by Ellis [40], namely $\Delta u = 0.78 \pm 0.02$, $\Delta d = -0.48 \pm 0.02$ and $\Delta s = -0.15 \pm 0.02$, i.e.

$$a_0 = a_0(q) (\Delta u + \Delta d + \Delta s) = 0.15 a_0(q),$$
$$a_1 = a_1(q) (\Delta u - \Delta d) = 1.26 a_1(q).$$

(2)

In other words the isovector component is renormalized as is expected for the axial current from weak interactions, while the isoscalar component is suppressed, consistent with European Muon Collaboration (EMC) effect [41, 42], i.e. the fact that only a tiny fraction of the spin of the nucleon is coming from the spin of the quarks (see, e.g., an update in a recent review [43]). Thus in general, barring very unusual circumstances at the quark level, the isovector component is expected to be dominant. From these amplitudes one is able to calculate the isoscalar and isovector nucleon cross section. It is for this reason that we started our discussion in the isospin basis and not the proton update in a recent review [43]. Thus in general, barring very unusual circumstances at the quark level, the isovector component is renormalized as is expected for the axial current from weak interactions.

In other words the isovector component is renormalized as is expected for the axial current from weak interactions, while the isoscalar component is suppressed, consistent with European Muon Collaboration (EMC) effect [41, 42], i.e. the fact that only a tiny fraction of the spin of the nucleon is coming from the spin of the quarks (see, e.g., an update in a recent review [43]). Thus in general, barring very unusual circumstances at the quark level, the isovector component is expected to be dominant. From these amplitudes one is able to calculate the isoscalar and isovector nucleon cross section. It is for this reason that we started our discussion in the isospin basis and not the proton update in a recent review [43]. Thus in general, barring very unusual circumstances at the quark level, the isovector component is renormalized as is expected for the axial current from weak interactions.

Thus, leaving aside the factor $F_{11}$, which will be taken care of explicitly in the expression for the event rate (see below), the nuclear static spin cross section becomes

$$\sigma_A^{\text{spin}} = \frac{\Omega_1^2 \sigma_1(N) + 2 \text{sign}(a_1 a_0) \Omega_0 \Omega_1 \sqrt{\omega(N) \sigma_1(N) + \Omega_0^2 \sigma_0(N)}}{3}.$$

(5)

where $\sigma_0(N)$ and $\sigma_1(N)$ are the elementary nucleon isoscalar and isovector cross sections. Instead of these two one could have written an equivalent expression in terms of the proton and neutron elementary cross sections [44] $\sigma_p$ and $\sigma_n$.

The above expressions look complicated. In most models, however, e.g. in the case the WIMP is the Lightest Supersymmetric Particle (LSP), one encounters $Z$ exchange and $Z - qq$ coupling are purely isovector. The same is true in models involving heavy neutrinos as WIMPs, e.g. Kaluza Klein theories in models with Universal Extra Dimensions [21]. In the latter case it is possible to have both an isoscalar and isovector component if the WIMP happens to be a vector boson. Only isovector amplitudes are predicted also in the case of exotic spin 3/2 particles [36]. Since as we have already mentioned the isoscalar nucleon cross section is expected to be suppressed, the above expression gets simplified to

$$\sigma_A^{\text{spin}} = \frac{\Omega_1^2 \sigma_1(N)}{3}.$$

(6)

This is the expression we are going to employ in this work.

Regarding the spin induced nucleon cross sections at this point there exist some experimental limits, namely for $^{129}$Xe and $^{131}$Xe [45] and $^{19}$F [46–50]. From the Xe data a limit is extracted on the elementary neutron SD cross section of $\sigma_n = 2 \times 10^{-40} \text{cm}^2 = 2 \times 10^{-4} \text{pb}$ and $\sigma_p = 2 \times 10^{-38} \text{cm}^2 = 1.0 \times 10^{-7} \text{pb}$ for the proton SD cross section, while from the F target a slightly smaller limit is extracted on the proton SD cross section, $\sigma_p = 1 \times 10^{-38} \text{cm}^2 = 1.0 \times 10^{-2} \text{pb}$.
These limits were based on nuclear physics considerations, namely the nuclear spin matrix elements in the proton neutron representation. This explains the difference of the two limits extracted from the Xe data. On the other hand, if the elementary amplitude is purely isovector, these limits would imply \( \sigma_1 = \sigma_p + \sigma_n = 1.02 \times 10^{-2} \text{pb} \). We should mention in passing that the nuclear matrix elements for \(^{19}\text{F}\) are expected to be much more reliable [27, 44]. Actually the problem of extracting the nucleon cross sections from the data will remain open until all the three nucleon cross sections (scalar, proton spin and neutron spin) can be determined along the lines previously suggested [51], after sufficient experimental information on at least three suitable targets becomes available. Anyway in the present work we will not commit ourselves to any particular model, but for orientation purposes we will use the value [36] of \( \sigma_1(N) \approx 1.7 \times 10^{-18} \text{cm}^{-2} = 1.7 \times 10^{-2} \text{pb} \).

### III. THE STRUCTURE OF THE \(^{83}\text{Kr}\) NUCLEUS

A complete calculation of the relevant spin structure should be done along the lines previously done for other targets [26], [52], [53], [54], [55], [56],[57] and more recently [58],[59], [60] in the the shell model framework. We will not concern ourselves with other simplified models, e.g schemes of deformed rotational nuclei [61].

A summary of some nuclear ME involved in elastic and inelastic scattering can be found elsewhere [36], [62].

In principle one may have to go a step further in improving the structure functions, since it has recently been found that in the evaluation of the ground state (gs) spin structure functions some additional input is needed, namely:

- One has to consider the nucleon form factor [27],[44] entering the isovector axial current:

\[
J = \frac{g_A(q)}{\frac{1}{2}A} \Sigma, \quad \Sigma = \sigma - \frac{(\sigma \cdot q) q}{q^2 + m_m^2}.
\]

If we choose as a \( z \)-axis the direction of momentum we find:

\[
J_m = \begin{cases} 
(1 - \frac{q^2}{q^2 + m_m^2}) \sigma_m, & m = 0 \\
\sigma_m, & m = \pm 1
\end{cases}
\]

Thus only the longitudinal component of the transition operator is modified by the inclusion of the nucleon form factor. Thus, even at sufficiently high momentum transfers, only 1/3 of the differential rate will be affected.

- One has to consider effects arising from possible exchange currents.

Such currents lead to effective 2-body contributions obtained in the context of Chiral Effective Field Theory (EFT) [59].

We will elaborate further on this point, however, since it has been shown that such effects are independent of the target nucleus [44]. Thus they can be adequately contained in a retardation factor of the isovector amplitude, which takes the value of about 0.8. Thus one can absorb such effects in the isovector nucleon spin cross section, which anyway in practice it may have to be extracted from experiment, once the spin induced rates have been observed. We expect such a treatment will also work in the structure functions involving transitions to excited states.

### IV. SHELL-MODEL INTERPRETATIONS

To interpret the experimental data, shell-model calculations have been carried out in the 28-50 valence shell composed of the \( 1p_{3/2}, 0f_{5/2}, 1p_{1/2}, 0g_{9/2} \) orbitals. The calculations have been performed with recently available effective interaction by Brown and Lisetskiy [63] and shell model code NuShellX [64]. The single-particle energies employed in conjunction with the jj44b interaction are -9.6566, -9.2859, -8.2695, and -5.8944 MeV for the \( 1p_{3/2}, 0f_{5/2}, 1p_{1/2}, 0g_{9/2} \) orbitals, respectively. The ground state is correctly reproduce by present calculation. The first excited \( 7/2^+ \) state is predicted at 100 keV, while corresponding experimental value is 9 keV.

In Table I, we have compared experimental \( B(E2) \) and \( B(M1) \) values. The overall agreement is reasonable, at least for \( B(E2) \). The calculated \( B(E2 : 7/2^+ \rightarrow 9/2^+) \) value is 11.62 W.u., while the corresponding experimental value is 21.3(17) W.u. The structure of \( 9/2^+ \) state is \( \nu(g_{9/2})^{-2} \) (with probability \( \sim 16\% \)). The same configuration is predicted for the first excited state (\( \sim 26\% \)). The calculated \( B(M1 : 7/2^+ \rightarrow 9/2^+) \) value is 0.0028 W.u., while the corresponding experimental value is 0.0095 W.u. The calculated values of the quadrupole and magnetic moments are shown in Table II. These results are in reasonable agreement with the available experimental data. In particular, they reproduce correctly the sign of the quadrupole and magnetic moments.
Table I: Calculated $B(E2)$ and $B(M1)$ values for $^{83}$Kr isotope with standard effective charges: $e_{\pi}^{\text{eff}}=1.5e$, $e_{\nu}^{\text{eff}}=0.5e$ and for $g_{s}^{\text{eff}}=g_{s}^{\text{free}}$ (the experimental $\gamma$-ray energies corresponding to these transitions are also shown).

| $J_i^+ \rightarrow J_f^+$ | $E_\gamma$ (keV) | $B(E2)(W.u.)$ | $B(M1)(W.u.)$ |
|--------------------------|----------------|--------------|--------------|
| $7/2^+ \rightarrow 9/2^+$ | 9.4            | 21.3(17)     | 11.62        |

Table II: Electric quadrupole moments, $Q_s$ (in $e$\text{b}$)$ and magnetic moments, $\mu$ (in $\mu$\text{N}$)$, (the effective charges $e_{\pi}=1.5$, $e_{\nu}=0.5$ and for $g_{s}^{\text{eff}}=g_{s}^{\text{free}}$ are used in the calculation).

| $J^+$  | $Q_{s,\text{exp}}$ | $Q_{s,j44b}$ | $\mu_{\text{exp}}$ | $\mu_{j44b}$ |
|--------|--------------------|--------------|---------------------|--------------|
| $9/2^+$| +0.26 (3)          | +0.34        | -0.970669 (3)       | -1.412       |
| $7/2^+$| +0.495 (10)        | +0.41        | -0.943 (2)          | -1.099       |

The thus obtained static spin MEs are

\[ \Omega_0 = 1.037, \quad \Omega_1 = -1.018 \] for elastic transitions,

\[ \Omega_0 = -4.880 \times 10^{-2}, \quad \Omega_1 = 4.421 \times 10^{-2} \] for inelastic transitions.

Looking at these matrix elements we notice the following:

- The nuclear wave functions do not favor the isoscalar contribution to overcome the expected suppression of the corresponding isoscalar amplitude in going from the quark to the nucleon level discussed above.

- The inelastic transition is not predominantly a Gamow-Teller-like transition (that is, driven by the $\sigma$ operator), but it is dominated by higher multipoles.

The disadvantage of small value of the spin ME in the inelastic transition may, however, be partly overcome by the fact that, unlike the EM decay of the excited state, a relatively high momentum can be transferred to the nucleus by the WIMP and the excited state structure function does not fall fast with the transferred momentum.

The structure functions relevant to our calculation are exhibited in Fig. 1.

V. TRANSITIONS TO EXCITED STATES

The expression for the elastic differential event rate is well known, see e.g. [36], [44]. For the reader’s convenience and to establish our notation we will briefly present the essential ingredients in the Appendix A. We should mention that as can be seen in the appendix the difference in the shape of the spectrum between the coherent and the spin induced one comes from nuclear physics. Since the square of the form factor and the elastic spin structure functions have approximately similar shapes, see Fig. 1, we expect the corresponding differential shapes to be the same, and only the scale to be different.

Transitions to excited states are normally energetically suppressed, except in some odd nuclei that have low lying excited states. Then spin mediated transitions to excited states are possible. The most favorable are expected to be those that, based on the total angular momentum and parity of the states involved, appear to be Gamow-Teller like transitions. A good possibility is the $7/2^+$ state of $^{83}$Kr, which is at 9.5 keV above the $9/2^+$ ground state.

A. Isotope considerations

Transitions to the first excited states via the spin dependent (SD) WIMP-nucleus interaction can occur in the case of some odd A targets, if the relevant excitation energy is $E \leq 100$ keV. This is due to the high velocity tail of the M-B distribution, so that a reasonable amount of the WIMP energy may be transferred to the recoiling nucleus.

Possible odd mass nuclei involved in DM detectors used for WIMP searches are the 57.6 keV state in $^{127}$I and the 39.6 keV state in $^{129}$Xe. The spin excitations of these states are not favored, because the dominant components of the relevant wave functions are characterized by $\Delta \ell \neq 0$, i.e. $\ell$ forbidden transitions. Nevertheless the spin transitions...
Figure 1: Elastic spin structure function $F_{ij}^e(E_R)$ for the isospin modes $i, j = 11, 01, 00$ as functions of the energy transfer in keV in the case of the target $^{83}$Kr (a). For comparison we present the square of the form factor entering the coherent mode (solid line). Note that the elastic structure functions, when normalized to unity at momentum transfer zero, are essentially independent of isospin. We also show the inelastic spin structure function $F_{ij}^{in}(E_R)$ (b). In this case the structure functions are not very much depressed as function of the energy transfer, compared to those of the elastic scattering.
are possible, due to the small components as seen from the M1 \( \gamma \) transition rates. Other possibilities are, of course, of interest, e.g. \(^{83}\)Kr is a good experimental candidate. We will see below that it can become a good liquid or gas detector. Thus it is quite realistic to study the inelastic excitations in this nucleus in the search for WIMPs via the SD interaction.

In fact the experimental observation of the inelastic excitation has several advantages. The experimental feasibility is discussed in section VIII.

Table III: Inelastic spin excitations of experimentally interesting targets

| Isotope | \( A \) (\%) | \( E \) (keV) | \( J_i \) | \( J_f \) | \( T_{1/2} \) (ns) |
|---------|-------------|-------------|---------|---------|-------------|
| \(^{83}\)Kr | 11.5 | 9.5 | 9/2\(^+\) | 7/2\(^+\) | 154 |
| \(^{127}\)I | 100 | 57.6 | 5/2\(^+\) | 7/2\(^+\) | 1.9 |
| \(^{129}\)Xe | 26.4 | 39.6 | 1/2\(^+\) | 3/2\(^+\) | 0.97 |
| \(^{125}\)Te | 7.07 | 35.5 | 1/2\(^+\) | 3/2\(^+\) | 1.48 |

B. Kinematics

The evaluation of the differential rate for the inelastic transition proceeds in a fashion similar to that of the elastic case discussed above, except:

1. The transition spin matrix element must be used.

2. The transition spin response function must be used. For Gamow-Teller like transitions, it does not vanish for zero energy transfer. So it can be normalized to unity, if the static spin value is taken out of the ME.

3. The kinematics is modified. The energy-momentum conservation reads:

\[
-\frac{q^2}{2\mu_r} + v\xi q - E_x = 0, \quad E_x = \text{excitation energy} \Leftrightarrow -\frac{m_A}{\mu_r} E_R + v\xi \sqrt{2m_A E_R} - E_x = 0
\]  

(9)

Where \( \xi \) is the cosine of the angle between the incident WIMP and the recoiling nucleus. From the above expression we immediately see that \( \xi > 0 \) as in the case of the elastic scattering. Furthermore the condition \( \xi < 1 \) imposes the constraint:

\[
v > \frac{E_x + \frac{m_A}{\mu_r} E_R}{\sqrt{2m_A E_R}}
\]

(10)

We thus find that for a given energy transfer \( E_R \) the minimum allowed WIMP velocity is given by:

\[
v_{\text{min}} = \frac{E_x + \frac{m_A}{\mu_r} E_R}{\sqrt{2m_A E_R}}
\]

(11)

while the maximum and minimum energy transfers are limited by the escape velocity in the WIMP velocity distribution. We find that:

\[
(E_R)_{\text{min}} \leq E_R \leq (E_R)_{\text{max}}
\]

(12)

with

\[
(E_R)_{\text{min}} = \frac{\mu_r^2}{m_A} \left( v_{\text{esc}}^2 - \frac{E_x}{\mu_r} - \sqrt{v_{\text{esc}}^4 - 2v_{\text{esc}}^2 \frac{E_x}{\mu_r}} \right), \quad (E_R)_{\text{max}} = \frac{\mu_r^2}{m_A} \left( v_{\text{esc}}^2 - \frac{E_x}{\mu_r} + \sqrt{v_{\text{esc}}^4 - 2v_{\text{esc}}^2 \frac{E_x}{\mu_r}} \right)
\]

(13)

In the case of elastic scattering we recover the familiar formulas:

\[
(E_R)_{\text{min}} = 0, \quad (E_R)_{\text{max}} = \frac{2\mu_r^2}{m_A} v_{\text{esc}}^2
\]
From the above expressions it is clear that for a given nucleus and excitation energy only WIMPs with a mass above a certain limit are capable of causing the inelastic transition, i.e.

$$m_X \geq m_A \left( \frac{1}{2} v_{\text{esc}}^2 \frac{m_A}{E_x} - 1 \right)^{-1}$$  \hspace{1cm} (14)

$$(m_X)_{\text{min}} = (4.6, 19, 34, 21) \text{ GeV for } ^{83}\text{Kr, } ^{125}\text{Te, } ^{127}\text{I, } ^{129}\text{Xe}$$

We find it simpler to deal with the phase space in dimensionless units. Noticing that $u = (1/2)q^2b^2$ and

$$\delta \left( \frac{-q^2}{2\mu_r} + v\xi q - E_x \right) = \delta \left( -\frac{u}{\mu_r b^2} + v\xi q - E_x \right) \leftrightarrow \frac{b}{\sqrt{2u}} \delta \left( \xi - \frac{E_x + u/\langle \mu_r b^2 \rangle}{\sqrt{2u}} \right)$$  \hspace{1cm} (15)

we find:

$$\int q^2 d\xi dq \delta \left( \frac{-q^2}{2\mu_r} + v\xi q - E_x \right) = \frac{1}{b^2 \sqrt{u}} du$$  \hspace{1cm} (16)

i.e. we recover the same expression as in the case of ground state transitions. The above constraints now read:

$$y > a \frac{u + u_0}{\sqrt{u}}$$  \hspace{1cm} (17)

$$u_0 = \mu_r E_x b^2, \quad a = \frac{1}{\sqrt{2\mu_r v_0 b}}, \quad u = \frac{E_R}{Q_0(A)}.$$  \hspace{1cm} (18)

It should be stressed that for transitions to excited states the energy of recoiling nucleus must be above a minimum energy, which depends on the escape velocity, the excitation energy and the mass of the nucleus as well as the WIMP mass. This limits the inelastic scattering only for recoiling energies above the values $(E_R)_{\text{min}}$. The minimum and maximum energy that can be transferred is:

$$u_{\text{min}} = \frac{1}{4} \left( \frac{E_{\text{esc}}}{a} - \sqrt{\left( \frac{E_{\text{esc}}}{a} \right)^2 - 4u_0} \right)^2, \quad u_{\text{max}} = \frac{1}{4} \left( \frac{E_{\text{esc}}}{a} + \sqrt{\left( \frac{E_{\text{esc}}}{a} \right)^2 - 4u_0} \right)^2$$  \hspace{1cm} (19)

The maximum energy transfers $u_{\text{max}}$ depend on the escape velocity $v_{\text{esc}} = 620\text{km/s}$. Here we have denoted $v_{\text{esc}} = y_{\text{esc}} v_0$, where $v_0$ is the characteristic velocity of the M-B distribution taken to be 220 km/s, i.e. $y_{\text{esc}} \approx 2.84$. The values $u_{\text{min}}, u_{\text{max}}, (E_R)_{\text{min}}$ and $(E_R)_{\text{max}}$ relevant for the inelastic scattering of $^{83}\text{Kr}$ and $^{125}\text{Te}$ are shown in Table IV. The minimum required and the maximum allowed energy transfer depend on the WIMP escape velocity. The dependence of the maximum is not crucial, since the contribution to the total rate becomes negligible at high energy transfers. The behavior of the minimum in the range of the existing limits of the escape velocities [65] is exhibited in Fig. 2 as a function of the escape velocity. From this figure we see the kinematical advantage (lower recoil energy needed for the inelastic process) as a result of the low excitation energy of $^{83}\text{Kr}$ compared to $^{125}\text{Te}$.

To avoid uncertainties arising from the relevant particle model, we will present the rate to the excited relative to that to the ground state (branching ratio). The differential event rate for inelastic scattering takes a form similar to the one given by Eq. 23 except that

$$\Omega_1 \rightarrow \Omega_1^{\text{inelastic}}, \quad F_{11}(u) \rightarrow F_{11}(u)^{\text{inelastic}}, \quad \Psi_0(a\sqrt{u}) \rightarrow \Psi_0 \left( a \frac{u + u_0}{\sqrt{u}} \right).$$

VI. SOME RESULTS

For purposes of illustration we will employ the nucleon cross section of $1.7 \times 10^{-26}\text{pb}$ obtained in a recent work [36], without committing ourselves to this or any other particular model. Another input is the WIMP density in our vicinity, which will be taken to be 0.3 GeV cm$^{-3}$. Finally the velocity distribution with respect to the galactic center will be assumed to be a M-B with a characteristic velocity $v_0 = 220\text{km/s}$ and an upper cut off (escape velocity) of $2.84v_0$. 

Figure 2: The minimum required energy transfer as a function of the escape velocity for $^{83}$Kr (a). For comparison we present the same quantity for $^{125}$Te (b). Regardless of the escape velocity $^{83}$Kr enjoys an advantage at the low energy transfer region.

Table IV: The kinematical parameters entering the inelastic scattering to the first excited state of $^{83}$Kr. For comparison we present the same quantities for $^{125}$Te.

| Target | Parameter | $m_A$ (GeV) |
|--------|-----------|-------------|
|        |           | 20  50 100 200 500 1000 |

A. The differential event rates

The differential event rates, perhaps the most interesting from an experimental point of view, depend on the WIMP mass, but we can only present them for some select masses. Our results for the elastic differential rates for typical WIMP masses are exhibited in Fig. 3a. For comparison we present the differential event rates for transition to the excited state in Fig. 3b. We will evaluate the branching ratio of the inelastic differential cross section to that of the ground state ignoring the coherent mode. We will restrict ourselves in the isovector transition. This is reasonable, since as we have already mentioned the isoscalar is absent in most particle models and even if it appears at the quark level it is expected to be suppressed [66] due to considerations related to the spin of the nucleon. In such a case the ratio becomes independent of the elementary nucleon cross section. The obtained results are exhibited in Fig. 4.
Figure 3: Energy spectrum for WIMP $^{83}$Kr elastic scattering (a) and that for the 9.4 keV excited state inelastic scattering (b) for WIMP masses 20, 50, 100, 200, 500 and 1000 GeV, increasing from top to bottom. The thick solid, solid, dotted, dashed-dotted, dashed and large-dot curves correspond to the above WIMP masses.
Figure 4: The ratio of the differential scattering rates, \( \frac{dR(\text{excited})}{dE_R} / \frac{dR(\text{gs})}{dE_R} \), in units of \( 10^{-5} \), as a function of the recoil energy \( E_R \) in keV in the case of the target \(^{83}\text{Kr}\) for \( y_{\text{esc}} = 2.5 \). Otherwise the notation is the same with that of Fig. 3. Note that the range of the allowed energy transfer depends on the WIMP mass. The dependence on the escape velocity is mild and it is not exhibited here.

B. Total rates

From expressions (26) and (27), we can obtain the total rates. It is instructive to start with a consideration of the branching ratio of the total rates, which for the reasons discussed above is going to be independent of the elementary nucleon cross section. Since the elastic scattering event rate is reduced by the threshold effects, but the inelastic scattering is not affected by such effects, we expect the branching ratio to be increasing as the threshold energy is increasing. The situation is exhibited in Fig. 5.

The total rates obtained assuming zero energy threshold are exhibited in Fig. 6 as functions of the WIMP mass.

VII. EXPERIMENTAL ASPECTS OF INELASTIC NUCLEAR SCATTERING RATES

In this section, we discuss experimental aspects of the spin dependent (SD) WIMP-nucleus interaction by measuring inelastic nuclear scattering. So far SD and SI WIMP interactions with nuclei have been studied experimentally by measuring nuclear recoils in elastic scatterings.

SD interactions may show fairly appreciable cross sections of inelastic spin excitations, as shown in previous sections. Experimentally, inelastic nuclear excitations provide unique opportunities for studying WIMPs exhibiting SD
interactions with hadrons. Experimentally, inelastic nuclear excitations provide unique opportunities for studying SD rates for WIMP-nuclear interactions. Inelastic excitations can, in principle, be studied by two ways: A singles measurement of both the nuclear recoil energy $E_R$ and the decaying $\gamma$-ray energy $E_\gamma$ in one detector, and B a coincidence measurement of the nuclear recoil and the $\gamma$-ray in two separate detectors in a fashion discussed in the earlier analysis [62]. In the case of $^{83}$Kr we will consider only option A.

The large energy signal is obtained by summing the nuclear recoil signal and the $\gamma$-ray signal. It is given as

$$E(\text{ex}) = E_\gamma + Q(E_R(\text{ex}))E_R(\text{ex}), \quad (20)$$

where $E_R(\text{ex})$ is the nuclear recoil energy, $E_\gamma$ is the excitation energy and $Q(E_R(\text{ex}))$ is the quenching factor for the recoil energy signal. It must be determined for each target and detector experimentally. An overall picture can be obtained by a phenomenological approach based on the Lindhard theory [67, 68], which is exhibited in Fig. 7. In most scintillation and ionization detectors, the quenching factor is as small as $Q(E_R(\text{ex})) \approx 0.1 - 0.05$. For $^{83}$Kr, the primary target considered in this work, the quenching factor is not important for a gaseous detector, but for a liquid or solid it is taken to be $0.08 - 0.1$. In the present work we will use a quenching factor of 0.08. We note, however, that, due to the low excitation energy, our conclusions about the inelastic transition are not affected much by the quenching factor.

Therefore it appears that the energy deposited is mainly the excitation energy. This is much larger than just the recoil energy signal of $E(\text{gr}) = Q(E_R(\text{gr}))$, which is quenched, depending on the detector.

The sharp rise of the energy spectrum at the energy of $E_\gamma + Q(E_{\text{min}})E_{\text{min}}$, where $E_{\text{min}}$ is the minimum energy transfer to the recoil nucleus. This makes it possible to identify the WIMP nuclear interaction. On the other hand, the recoil energy spectrum $E_R(\text{gr})$ is continuum like background at the low energy region, and thus is hard to be identified.

$E(\text{ex})$ is well above the detector threshold $E(\text{th})$, while the main part of $E(\text{gr})$ is cutoff by $E(\text{th})$. Accordingly, the event rate $R(\text{ex})$ is about the same order of magnitude as $R(\text{gr})$ for WIMPs exhibiting SD dependent interaction.

Figure 5: The ratio of the total scattering rates, $R(\text{excited})/R(\text{gs})$, as a function of the WIMP mass in GEV for $y = 2.84$ in the case $^{83}$Kr. From bottom up the threshold values are 0, 1, 2, 4, 7 and 10 keV. Only the spin mode has been taken into account. The quenching factor is expected to increase this ratio in the case of non zero threshold, but it has not been included in these plots.
Figure 6: We show for the target $^{83}$Kr the time average total rate as a function of the WIMP mass in GeV obtained in the case of elastic scattering (a) and inelastic scattering (b), assuming a zero energy threshold. Note that the maximum in the case of the inelastic scattering occurs at a higher mass compared to the location of the maximum for the ground state transition.
although the inelastic cross section is much smaller than the elastic one.

The typical energy spectra to be measured experimentally for the elastic and inelastic transitions of $^{83}\text{Kr}$ are shown in Fig 8. Here we assumed detectors with the quenching factor of $Q=0.08$ and the energy threshold of $E(\text{th}) = 1.6$ keV. The yield on the y axis is the one per unit energy of the electron equivalent energy, i.e. $QE_R$ and the energy on the x axis is the electron equivalent energy. To cover a wide energy transfer regime we used semi-logarithmic plot. One can clearly see that the inelastic scattering is favored above 30 keVee recoil energy for sufficiently heavy WIMPs. This trend should be compared with results obtained previously in the case of the targets $^{129}\text{Xe}$ and $^{127}\text{I}$, which have appeared elsewhere [62]. Thus we see that the smallness of the spin ME in the case of $^{83}\text{Kr}$ is not completely compensated by the favorable energy dependence of its inelastic spin structure function and the low excitation energy.

We should mention that a search for inelastic WIMP nucleus scattering on $^{129}\text{Xe}$ using data from the XMASS-I experiment has recently appeared [69]. These authors set an upper limit of 3.2 pb for the inelastic nucleon cross section. This large value has nothing to do with the particle model, but it is a manifestation of the unfavorable kinematics involved in the inelastic case.

VIII. EXPERIMENTAL FEASIBILITY

The main purpose of the research described in this article is to explore the feasibility of an experiment to search for Cold Dark Matter via an inelastic excitation of a nuclear target. The isotope $^{83}\text{Kr}$ was chosen for two reasons: first, it has a low energy M1 transition from the $7/2^+$ first excited state at 9.4-keV to the $9/2^+$ ground state; second, in the liquid state it is a fairly good scintillation detector material. The disadvantage of this choice is that the natural abundance of $^{83}\text{Kr}$ is only 11.5% which will require isotopic enrichment. In addition any content of the ubiquitous radioactive isotope $^{85}\text{Kr}$ will render a sensitive search ineffective. Even the isotopic enrichment of Kr gas from the usual sources will never be free enough from $^{85}\text{Kr}$ to allow a sensitive experiment. Fortunately, a recent discovery by other researchers can very probably be used to ameliorate this difficulty. First, we discuss the scintillation properties of liquid Kr, and then possible new sources of low-radioactive Kr gas. The scintillation and other physical properties of liquid Kr has been well studied and published in the literature [70]-[71]. It has been shown by independent groups [70] [72] that the addition of a few percent by mass of Xe enhances the fast component of scintillation of LKr by a factor of approximately 10. Considering the long lifetime of the $7/2^+$ to $9/2^+$ ground-state decay in $^{83}\text{Kr}$, the pulse shape distortion might be utilized to provide partial background rejection as discussed in another case [73]. Nevertheless, this
Figure 8: Energy spectrum for WIMP $^{83}$Kr elastic scattering with an energy threshold $E(th) = 1.6$ keV is shown in panel (a). The energy spectrum for inelastic scattering to the 9.4 keV excited state is exhibited in panel (b). The quenching factor employed was $Q=0.08$. The x and y scales are the electron-equivalent energy and the rate per unit electron equivalent energy. Note that the maximum allowed energy transfer depends on the WIMP mass. For a heavy WIMP it can reach about 60 keVee, but it falls real fast with the energy transfer. Otherwise the notation is the same as in Fig. 3.
advantage would be minimal in the case that the background from $^{85}$Kr was not negligible. In the usual case, sources of krypton and argon for industrial use are obtained by distillation of atmospheric air, which contains radioactive $^{85}$Kr (10.75y) and $^{39}$Ar (269y). These contaminations are unacceptable for use in ultra-low background experiments. It is a well-known fact in the geology and geochemistry community that through petroleum exploration, very large deep underground accumulations of CO$_2$ have been discovered in the greater Colorado Plateau and in the Southern Rocky Mountain Region [74]. Recently the Princeton-lead Darkside Collaboration has been successful in working with industry to extract ultra-low radioactive background argon from large volumes of CO$_2$ using a Vacuum Pressure Swing Absorption plant [75],[76]. In the case of Kr, this would be the input gas for the isotopic enrichment. These facts imply the possibility of a sensitive search for the Cold Dark Matter excitation of $^{85}$Kr to the first excited state and the detection of the deexcitation 9.4-keV gamma ray. However, the extraction of the Kr from the deep underground CO$_2$, as well as the requirement of isotopic enrichment would be far more costly than the extraction of $^{40}$Ar, which has an isotopic abundance of 100%. Accordingly, a research and development study would have to be undertaken to determine the technical and cost feasibility of this experimental approach. However, of the 30 isotopes discussed by Ellis, Flores and Lewin [39] $^{85}$Kr is one of the few for which there are clear paths to building a large detector.

IX. CONCLUDING REMARKS

WIMPs have extensively been studied, so far, by measuring elastic nuclear recoils involving both by SI and SD interactions. The SI elastic scattering of WIMPs is coherent scattering, thus the cross section is enhanced by the factor $A^2$ with $A$ being the nuclear mass number. On the other hand the elastic spin induced (SD) cross section of WIMPs is, in general, smaller by 2-3 orders of magnitude than that for SI WIMPs because the spin induced rates do not depend on $A^2$, i.e. they do not exhibit coherence. It may, however, compete with the coherent scattering in models in which the spin induced nucleon cross section is much larger than the one due to a scalar interaction. We have seen that there exist viable such particle models. In such cases the inelastic WIMP-nucleus scattering becomes important.

Indeed the inelastic scattering via spin interaction provides a new opportunity for detecting WIMPs via the SI interaction. Experimentally, the observation of both the nuclear recoils and the gamma ray following the the de-excitation of the populated state results in a large energy signal of the unquenched $E_\gamma$ and a sharp rise of the energy spectrum at around $E_\gamma$. Even though the SD inelastic cross section is smaller than the SD elastic one, the inelastic event rate is expected to be comparable to the elastic one, since the inelastic signal is well beyond the detector threshold energy, while the elastic signal is mostly cut off by the detector threshold.

In the present paper we discussed mainly the inelastic excitations of $^{83}$Kr. For completeness we mention that other possible isotopes, in addition to the $^{127}$I and $^{129}$Xe discussed previously [62], is the $^{73}$Ge, in high energy resolution Ge detectors, and $^{125}$Te currently under study. In short, the present paper, in conjunction with the earlier calculations [62], indicates that the inelastic scattering opens a new powerful way to search for WIMPs via the SD interaction with the nuclear targets.

Acknowledgments: One of the authors (JDV) is indebted to H. Ejiri for enlightening discussions and his comments, especially on the quenching factors, and the Physics Department of the University of S. Carolina for their support and hospitality. The authors are grateful to Frank Calaprice for very helpful discussions. X. APPENDIX A: THE FORMALISM FOR THE WIMP-NUCLEUS DIFFERENTIAL EVENT RATE

The expression for the differential event rate is well known, see e.g. [36][44]. For the reader’s convenience and to establish our notation we will briefly present the essential ingredients here. We will begin with the more familiar time averaged coherent rate, which can be cast in the form:

$$\frac{dR_0}{dE_R} = \rho_\chi \frac{m_t}{m_\chi} \frac{\mu_\chi}{\mu_p} \left( \frac{\mu_\chi}{\mu_p} \right)^2 \sqrt{1 - v^2} > \frac{1}{Q_0(A)} A^2 \sigma_{coh}^{\chi} \left| \left( \frac{dt}{du} \right) \right|_{coh} , \left( \frac{dt}{du} \right) \right|_{coh} = \sqrt{\frac{2}{3}} a^2 F^2(u) \Psi_0(a \sqrt{u})$$  (21)

where with \( \mu_\chi \) (\( \mu_p \)) the WIMP-nucleus (nucleon) reduced mass and \( A \) is the nuclear mass number. \( m_\chi \) is the WIMP mass, \( \rho_\chi \) is the WIMP density in our vicinity, assumed to be 0.3 GeV cm\(^{-3}\), and \( m_t \) the mass of the target. \( u \) is the recoil energy \( E_R \) in dimensionless units introduced here for convenience, \( u = \frac{1}{2}(q)^2 = Am_p E_R \), with \( A \) the nuclear mass number of the target and \( b \) the nuclear harmonic oscillator size parameter characterizing the nuclear wave function. It simplifies the expressions for the nuclear form factor and structure functions. In fact:

$$u = \frac{E_R}{Q_0(A)} , \quad Q_0(A) = [m_p A b^2]^{-1} = 40 A^{-4/3} \text{ MeV}$$  (22)

The factor \( \sqrt{2/3} \) in the above expression is \( v_0/\sqrt{\langle v^2 \rangle} \) since in Eq. (21) the WIMP flux is given in units of \( \sqrt{\langle v^2 \rangle} \) appears. In the above expression \( a = (\sqrt{2} \mu_\chi b v_0)^{-1} \), \( v_0 \) the velocity of the sun around the center of the galaxy and \( F(u) \) is the nuclear form factor. Note that the parameter \( a \) depends both on the WIMP mass, the target and the velocity distribution.

For the axial current (spin induced) contribution one finds for the elastic WIMP-nucleus scattering:

$$\frac{dR_0}{dE_R} = \rho_\chi \frac{m_t}{m_\chi} \frac{\mu_\chi}{Am_p} \left( \frac{\mu_\chi}{\mu_p} \right)^2 \sqrt{1 - v^2} > \frac{1}{Q_0(A)} A^2 \sigma_{spin}^{\chi} \left| \left( \frac{dt}{du} \right) \right|_{spin} , \left( \frac{dt}{du} \right) \right|_{spin} = \sqrt{\frac{2}{3}} a^2 F_{11}(u) \Psi_0(a \sqrt{u})$$  (23)

where \( F_{11} \) is the isovector spin response function, i.e. \( F_{el} \) for the elastic case and \( F_{in} \) for the inelastic one. We notice that the only difference in the shape of the spectrum between the coherent and the spin comes from nuclear physics. Since the square of the form factor and the spin structure functions have approximately similar shapes, we expect the corresponding differential shapes to be the same, and only the scale to be different.

The function \( \Psi_0(x) \) is defined by \( \Psi_0(x) = q(v_{min}, v_E(\alpha))/v_0 \), where \( v_0 \) is the velocity of the sun around the center of the galaxy. \( q(v_{min}, v_E(\alpha)) \) depends on the velocity distribution in the local frame through the minimum WIMP velocity for a given energy transfer, i.e.

$$v_{min} = \sqrt{\frac{A m_p E_R}{2 \mu_\chi^2}}$$  (24)

The above way of writing the differential event rates we have explicitly separated the three important factors:
• the kinematics,
• the nuclear cross section $A^2\sigma_N$ or $\sigma^\text{spin}_A$
• the combined effect of the folding of the velocity distribution and the form factor or the nuclear structure function.

For the Maxwell-Boltzmann (M-B) distribution in the local frame it is defined as follows:

$$g(v_{\text{min}}, v_E) = \frac{1}{(\sqrt{\pi}v_0)^{(3)}} \int_{v_{\text{min}}}^{v_{\text{max}}} e^{-(v^2+2v_E v_E+\frac{v_E^2}{v_0})/v_0^2} v dv d\Omega,$$

$$v_{\text{max}} = v_{\text{esc}},$$

(25)

where $v_E$ is the velocity of the Earth, including the velocity of the sun around the galaxy. We have neglected the velocity of the Earth around the sun, since we ignore the time dependence (modulation) of the rates. The above upper cut-off value in the M-B is usually put in by hand. Such a cut-off comes in naturally, however, in the case of velocity distributions obtained from the halo WIMP mass density in the Eddington approach [77], which, in certain models, resemble a M-B distribution [78].

Integrating the above differential rates we obtain the total rate including the time averaged rate for each mode given by:

$$R_{\text{coh}} = \frac{\rho_x}{m_x} \frac{m_t}{Am_p} \left( \frac{\mu_r}{\mu_p} \right)^2 \sqrt{<v^2> A^2 \sigma^\text{coh}_N} t_{\text{coh}}, \quad t_{\text{coh}} = \int_{E_{\text{th}}/Q_0(A)}^{(y_{\text{esc}}/a)^2} \frac{dt}{du}_{\text{coh}} du,$$

(26)

$$R_{\text{spin}} = \frac{\rho_x}{m_x} \frac{m_t}{Am_p} \left( \frac{\mu_r}{\mu_p} \right)^2 \sqrt{<v^2> \sigma^\text{spin}_A} t_{\text{spin}}, \quad t_{\text{spin}} = \int_{E_{\text{th}}/Q_0(A)}^{(y_{\text{esc}}/a)^2} \frac{dt}{du}_{\text{spin}} du,$$

(27)

for each mode (spin and coherent). $E_{\text{th}}(A)$ is the energy threshold imposed by the detector.

These expressions contain the following parts: i) The gross properties and kinematics ii) The parameter $t$, which contains the effect of the velocity distribution and the nuclear form factors iii) The WIMP-nuclear cross sections $A^2\sigma_N$ or $\sigma^\text{spin}_A$. The latter, contains the nuclear static spin ME. From the latter the elementary nucleon cross sections can be obtained, if one mode becomes dominant as already mentioned above. Anyway using the values for nucleon cross sections, $\sigma^\text{coh}_N$ in Eq. (26) and $\sigma^\text{spin}_A$ in Eq. (27), we can obtain the total rates.

Conversely, if only one mode is dominant, one can extract from the data the relevant nucleon cross section (coherent, spin isoscalar or spin isovector) or obtain exclusion plots on them.
