A new class of chiral materials hosting magnetic skyrmions beyond room temperature

Y. Tokunaga1,†, X.Z. Yu1, J.S. White2, H.M. Rønnow1,3, D. Morikawa1, Y. Taguchi1 & Y. Tokura1,4

Skyrmions, topologically protected vortex-like nanometric spin textures in magnets, have been attracting increasing attention for emergent electromagnetic responses and possible technological applications for spintronics. In particular, metallic magnets with chiral and cubic/tetragonal crystal structure may have high potential to host skyrmions that can be driven by low electrical current excitation. However, experimental observations of skyrmions have been limited to below room temperature for the metallic chiral magnets, specifically for the MnSi-type B20 compounds. Towards technological applications, transcending this limitation is crucial. Here we demonstrate the formation of skyrmions with unique spin helicity both at and above room temperature in a family of cubic chiral magnets: β-Mn-type Co-Zn-Mn alloys with a different chiral space group from that of B20 compounds. Lorentz transmission electron microscopy, magnetization and small-angle neutron scattering measurements unambiguously reveal formation of a skyrmion crystal under application of a magnetic field in both thin-plate and bulk forms.
Skyrmions with topologically non-trivial spin textures have been observed or proposed to exist in various magnets due to different mechanisms, such as magnetic dipolar interaction, antisymmetric spin exchange or so-called Dzyaloshinskii–Moriya (DM) interaction, frustrated exchange interaction and four-spin exchange interactions. In metallic compounds, skyrmions induce fictitious magnetic fluxes acting on the conduction electrons, thereby inducing the so-called topological Hall effect. Conversely, an applied electric current can induce a flow of skyrmions, with a threshold current density, which is 5–6 orders of magnitude smaller than that necessary for driving magnetic domain walls in ferromagnets. This property can be understood to arise from the theoretically predicted topological features of skyrmions. Among the various skyrmions, those induced by the DM interaction are particularly interesting due to their relatively small size (<150 nm) and fixed unique helicity (spin swirling direction). Theoretically, a number of helical magnets mediated by the DM interaction and with non-centrosymmetric crystallographic symmetries are predicted to be good candidates for hosting stable skyrmions. In spite of such anticipation, experimental observations of skyrmions in non-centrosymmetric bulk magnets have been limited to only B20-type alloys and Cu$_2$OSeO$_3$, all of which have the same cubic chiral space group $P4_3_2$. Their helical transition temperatures ($T_c$), and hence the maximum formation temperatures of skyrmions, are below room temperature (at most $\sim 278$ K in FeGe). The sub-ambient $T_c$ is a bottleneck for the integration of skyrmions in non-centrosymmetric magnets into practical spintronics devices. Therefore, new systems with higher $T_c$ are required.

One promising strategy to discover new DM helimagnets that host skyrmions above room temperature is to revisit non-centrosymmetric crystals that have been reported to be ferromagnetic above room temperatures. Similar to the case of B20 alloys and Cu$_2$OSeO$_3$, the DM interaction combined with the chiral crystal structure might turn an otherwise ferromagnetic phase into a helimagnetic one with long magnetic periodicity, and thus possibly host magnetic skyrmions under the magnetic field.

One such example is Co$_{10}$Zn$_{10}$ with $\beta$-Mn-type structure, which belongs to another cubic chiral space group $P4_3_2$, depending on its handedness, and which contains 20 atoms in the unit cell distributed across two kinds of

![Figure 1](image-url)

**Figure 1 | Crystal structure and helical magnetic order in the $\beta$-Mn-type Co-Zn-Mn alloys.** (a,b) Schematic of $\beta$-Mn-type structure with (a) $P4_3_2$ and (b) $P4_3_2$ space group, dependent on its handedness (chirality). It contains two crystallographic sites, that is, 8c with the three-fold site symmetry occupied by Co atoms (indicated by blue circle) and 12d with the two-fold site symmetry occupied by both Zn and Co atoms (indicated by grey circles) in the case of Co$_{10}$Zn$_{10}$ (ref. 29). (c) Temperature dependence of the magnetization for a series of polycrystalline Co-Zn-Mn alloys measured at $H = 20$ Oe on cooling. (d,e) Small-angle neutron scattering (SANS) images for polycrystalline samples of Co$_{10}$Zn$_{10}$ and Co$_{10}$Zn$_{7}$Mn$_3$, at $T = 317$ K, $H = 300$ Oe and $\tau = 120$ K, $H = 250$ Oe, respectively. The magnetic field direction is perpendicular to the neutron beam, which is itself into the page. (f) Composition dependence of the helical ordering temperature (filled blue circles) and helical pitch obtained by the SANS measurements (filled red squares) and LTEM observations (open red circles), respectively.
crystallographic sites. One is 8c with the three-fold site symmetry, and which is occupied by Co atoms, while the other is 12d with the two-fold site symmetry and occupied by both Zn and Co atoms. Co10Zn10 has been reported to be a ferromagnet with $T_c \approx 420$ K and the Co magnetic moments ($\sim 0.85 \mu_B$ per Co atom) ordered along $<100>$ according to neutron diffraction measurements. It has also been reported that the Co-Zn-Mn ternary system crystallizes in the $\beta$-Mn-type structure over a relatively wide composition range, and with $T_c$ dependent on the compositional ratio.

In this study, a series of $\beta$-Mn-type Co-Zn-Mn alloys are prepared and investigated in detail. As a result, the formation of chiral skyrmions is unambiguously demonstrated in both bulk and thin plate forms at and above room temperature. These results overcome limiting factors in terms of both operating temperature and materials variation, and hence can be an important step, towards the technological application of magnetic skyrmions for spintronics devices.

Results

Temperature dependence of magnetization. All prepared samples were confirmed to be of $\beta$-Mn-type, whose structure is depicted in Fig. 1a,b. Figure 1c shows the temperature dependence of the magnetization for selected samples measured in field-cooling runs. $T_c$ for Co10Zn10 is $\approx 462$ K, which is higher than the reported value ($\approx 420$ K, ref. 29), possibly due to a slight difference in the composition. On substituting Co and Zn with Mn, $T_c$ systematically decreases and Co6Mn6Zn8 no longer shows ferromagnetic-like behaviour. Magnetization measured at this magnetic field ($H = 20$ Oe) is observed to decrease at low temperatures in many samples, but this tendency is mostly suppressed for $H = 1$ kOe. Whether there is a second transition or not at low temperature remain a topic for future investigations.

Demonstration of the helimagnetic nature. To elucidate the possible helical nature of the magnetic ordering in these

![Figure 2](https://example.com/figure2.png)

**Figure 2 | Lorentz transmission electron microscopy (LTEM) of skyrmion crystal.** (a,b) LTEM image at 283 K on (111) plane of Co8Zn8Mn4 taken with under-focused condition at $H = 0$ and 400 Oe, respectively. (c-f) LTEM image at 345 K on (110) plane of Co9Zn9Mn2 taken with under-focused condition obtained at (c) $H = 0$ and (d) 650 Oe, and (f) with over-focused condition at $H = 650$ Oe. In (c), the dark band running diagonally across the image is the diffraction contrast and not of magnetic origin. (e) Colour map of in-plane components of the magnetic induction (which reflects in-plane magnetization) at $H = 650$ Oe deduced from TIE analysis of the images (d) and (f). (a-f) Scale bars, 200 nm. (g) Observed convergent-beam electron diffraction (CBED) pattern of Co9Zn9Mn2 taken with the [111] incidence from the same specimen area where the LTEM images (c-f) were obtained. (h,i) Simulated CBED patterns assuming the space group No. 213 (P4$_3$32) and No. 212 (P4$_3$32), respectively. (j-l), (m-o) and (p-r) are magnified images for the selected areas (surrounded by blue, red and green dotted rectangles) of (g), (h) and (i), respectively. (k) is based on another picture with different exposure time for the purpose of avoiding intensity saturation. Characteristic structures to be compared between experimental result and simulations are indicated by blue and red triangles in (j-r). Magnified images of the simulated pattern show significant differences for each crystal chirality. The simulated CBED pattern using P4$_3$32 (see m-o) shows a good agreement with the experimental one (see j-l).
compounds, we have performed small-angle neutron scattering (SANS) measurements. Figure 1d,e show typical SANS images obtained from polycrystalline pieces of Co$_{10}$Zn$_{10}$ and Co$_{7}$Zn$_{7}$Mn$_{6}$ under respective magnetic fields of 300 and 250 Oe applied perpendicular to the incident neutron beam direction. In the vicinity of the Q = 0 position, pairs of magnetic reflections are clearly observed nearly along the magnetic field direction, demonstrating the helical (or more precisely, conical due to the presence of the magnetic field) nature of the spin ordering in this system. The slight tilting of the peaks relative to the horizontal field direction demonstrates presence of weak magnetic anisotropy. As shown in Fig. 1f, the helical periodicity (λ) determined from the positions of the magnetic reflections shows a systematic change from λ ~ 185 nm for Co$_{10}$Zn$_{10}$ to λ ~ 115 nm for Co$_{7}$Zn$_{7}$Mn$_{6}$. This can be consistently understood as a decrease in the dominant ferromagnetic exchange interaction (J), which is reflected in the decrease of $T_c$. As a result, the periodicity which is given by J/D (where D is the DM interaction) also decreases. It is to be noted that all the compounds of Co$_{10-x/2}$Zn$_{10-x/2}$Mn$_{x}$ are good metals showing resistivity of 140–280 $\mu$Ωcm at room temperature. A detailed transport study is currently in progress.

**Formation of the chiral skyrmion above room temperature.** Since the system is found to be a cubic DM helimagnet, the formation of skyrmions is anticipated on application of the magnetic field in analogy to the case of B20-type (MnSi-type) alloys$^{6,7,27}$ and Cu$_2$OSeO$_3$ (refs 21,22). To demonstrate directly the formation of skyrmions in this system, real-space observations by Lorentz transmission electron microscopy (LTEM) have been performed for a thin-plate sample with thickness of <150 nm. In LTEM the under- and over-focusing of the deflected electron beam can reveal magnetic contrast, which has proven an efficient way to investigate skyrmion textures$^7$. A thin-plate specimen was sliced out from a polycrystalline ingot consisting of single-crystalline grains as large as several tens to hundred $\mu$m$^3$, and LTEM observations were performed for single-crystalline areas of larger than 100 $\mu$m$^2$ with specific crystallographic axes fortuitously normal to the thin plate.

**Figure 3 | Magnetic phase diagrams of bulk and thin-plate forms.** (a) Temperature dependence of isothermal dM/dH versus H curves for a polycrystalline piece of Co$_{10}$Zn$_{10}$Mn$_{5}$. (b) Magnetic phase diagram of the bulk sample in magnetic field versus temperature plane as deduced from dM/dH curves. (c–e) LTEM images on (111) plane of Co$_{10}$Zn$_{10}$Mn$_{5}$ taken with under-focused condition in H = 0.7 kOe applied normal to the plane at (c) T = 295 K, (d) 315 K and (e) 320 K, respectively. (d) Scale bar, 200 nm. (f), (g) and (h) are Fourier transforms of the LTEM images c, d and e respectively. (i) Contour plot of skyrmion density of the Co$_{10}$Zn$_{10}$Mn$_{5}$ (111)-thin plate in H versus T plane as deduced from LTEM observations obtained by counting the number of skyrmions in the area of ~120 $\mu$m$^2$ at each temperature and magnetic field. Some regions within the area contained dense SkX as in image d but other regions did not, making the average density smaller than expected from the image d. In the present bulk magnetization measurement, demagnetization factor (N) is ~0.1 from the sample shape, whereas N ~1 in the thin-plate form for LTEM observation. Taking the magnitude of the magnetization in this sample into consideration, it explains factor of 7–8 difference in the threshold external magnetic field for formation of the SkX phase in the bulk form (b) and thin-plate form (i).

NATURE COMMUNICATIONS | DOI: 10.1038/ncomms8638 | www.nature.com/naturecommunications
Figure 4 | Formation of the skyrmion crystal confirmed by small-angle neutron scattering (SANS). (a) Temperature dependence of a.c.-magnetic susceptibility versus magnetic field measured in $H \parallel [110]$ for a single-crystalline piece of $\text{Co}_8\text{Zn}_8\text{Mn}_4$. Hysteresis on increasing and decreasing magnetic field is indicated by arrows. The magnetic field region sandwiched by dotted lines indicates the skyrmion crystal phase. (b,c) SANS images for a single-crystalline sample of $\text{Co}_8\text{Zn}_9\text{Mn}_3$ at 317 K obtained at $H = 0$ and $H = 150$ Oe, respectively. $H$ and the incident neutron beam are parallel with each other and both along [110] direction. The horizontal and vertical axes of the SANS images correspond to the [001] and [110] crystal directions, respectively.

Figure 2a,b show the LTEM images for the (111) grain of $\text{Co}_8\text{Zn}_9\text{Mn}_3$ taken in the under-focus condition at 283 K. At $H = 0$ (Fig. 2a), a magnetic stripe structure is observed with a periodicity ($\sim 124$ nm) that is in excellent agreement with the SANS result ($\sim 125$ nm). On applying $H = 400$ Oe normal to the plate, the emergence of a skyrmion crystal (SkX) is clearly observed (Fig. 2b).

Figure 2c–f show the LTEM images obtained for a (110) grain of $\text{Co}_8\text{Zn}_9\text{Mn}_3$, there is no discernible magnetic contrast at $H = 0$ in the region shown in Fig. 2c in spite of $T < T_C$, and magnetic stripes develop only in limited areas at this temperature (not shown). Considering the fact that LTEM is only susceptible to the in-plane components of the magnetic induction, which reflects in-plane magnetization that does not cancel out when summed up along the thickness direction of the plate, a possible assignment of this phase is a helix with propagation vector directed normal to the plane, as conjectured from observations in the bulk $\text{B}_2\text{O}_3$ compounds. On application of magnetic field, however, a SkX emerges despite the absence of a helical structure with in-plane propagation vector at $H = 0$. Figure 2d,f are under- and over-focused images, respectively, taken at $H = 650$ Oe, where the contrast is inverted from each other, confirming their magnetic origin. Figure 2e is a colour map of the in-plane magnetic induction (reflecting magnetization) components deduced from Fig. 2d,f by use of a transport-of-intensity equation analysis. Notably, the formation temperature (e.g., 345 K) of skyrmions for $\text{Co}_8\text{Zn}_10\text{Mn}_2$ here is well above room temperature.

Convergent-beam electron diffraction (CBED) patterns can be utilized to assign the crystal chirality of the region where the LTEM image of $\text{Co}_8\text{Zn}_10\text{Mn}_2$ was taken. Figure 2g shows the experimental CBED pattern with the [111] incidence, which has three-fold symmetry. The simulated CBED patterns for the possible crystal chiralities of $\text{P}_4_3\text{P}_2$ and $\text{P}_4_3\text{S}_2$ are shown in Fig. 2h,i, respectively. The magnified images (Fig. 2j–r) display significant differences that are dependent on the crystal chirality. The CBED pattern obtained experimentally (Fig. 2g) shows good agreement with the simulated pattern for the crystal chirality of $\text{P}_4_3\text{S}_2$ (Fig. 2h). The observed region was further shown to be a single crystallographic domain, and therefore of unique crystal chirality. This unique crystal chirality is hence reflected by the unique sign of the DM interaction so that the magnetic helicity of the skyrmions is fully aligned over the whole region (Fig. 2e), similar to the case of the other cubic chiral magnets.

**Magnetic phase diagrams in the bulk and thin-plate form.** The signature of the SkX formation in bulk specimens was also observed by magnetization measurements. Figure 3a shows isothermal $dM/dH$ versus $H$ curves measured at different temperatures for a polycrystalline piece of $\text{Co}_8\text{Zn}_9\text{Mn}_3$. Between $\sim 311$ and $\sim 320$ K, a characteristic dip structure can be clearly seen at $\sim 100$ Oe, signalling the formation of the SkX in analogy with the $\text{B}_2\text{O}_3$-type alloys and $\text{Cu}_2\text{OSeO}_3$ systems. The magnetic phase diagram can be established from a contour plot of $dM/dH$, as shown in Fig. 3b. The SkX phase in the bulk appears in a relatively narrow temperature window with a width of $\sim 9$ K just below the helical ordering temperature. These features are in accordance with the phase diagram of bulk $\text{B}_2\text{O}_3$ alloys and $\text{Cu}_2\text{OSeO}_3$ (refs 21,22), and suggest that thermal fluctuations play a crucial role in stabilising the SkX phase also in this system of bulk form.

---

**Figure 5**

- **a** shows the CBED pattern obtained experimentally (Fig. 2g) shows good agreement with the simulated pattern for the crystal chirality of $\text{P}_4_3\text{S}_2$ (Fig. 2h).
To observe directly the SKX and uncover the influence of dimensionality on its stability, the phase diagram of a (111) thin plate (~150 nm) of Co$_8$Zn$_{10}$Mn$_2$ was studied with the use of LTEM. Figures 3c–e and 3f–h show typical LTEM images and their Fourier transformed images taken at $H = 0.7$ kOe. At $T = 295$ K, a stripe structure with weak contrast in real space (Fig. 3c) and broad peaks in Fourier space (Fig. 3f) is observed, suggesting the system to be in the helical phase. At 315 K (Fig. 3d,g), the formation of the SKX with hexagonal symmetry is clearly observed. Further increase of the temperature to 320 K (Fig. 3e,h) results in the disappearance of magnetic contrast as the system enters the paramagnetic phase. Figure 3i shows a contour (Fig. 3e,h) results in the disappearance of magnetic contrast as the system enters the paramagnetic phase. Figure 3i shows a contour plot of the skyrmion density as a function of magnetic field and temperature. The magnetic field range required to induce the SKX phase in the thin plate is significantly increased compared with the bulk case due to the demagnetization factor of the plate-like phase in the thin plate.

Magnetization measurements. Magnetization and a.c.-susceptibility were measured by a superconducting quantum interference device magnetometer (MPMS3, Quantum Design) equipped with oven and a.c.-susceptibility measurement options.

**SANS measurements.** The long-wavelength magnetic structures in bulk samples of Co$_8$Zn$_{10}$Mn$_2$ were measured using the SANS instrument SANS-1 at the Swiss Spallation Neutron Source, Paul Scherrer Institute, Switzerland. In a typical instrument setup, neutrons of wavelength 10 Å were selected with a full-width at half-maximum spread (Δ220) of ~10%, and collimated over a distance of 18 m before the sample. The scattered neutrons were collected by a position-sensitive multi-detector placed 18 m behind the sample. Polycrystalline ingot samples of Co$_8$Zn$_{10}$Mn$_2$, and single crystals samples of Co$_8$Zn$_{10}$Mn$_2$, were mounted inside a horizontal field cryomagnet that was installed on the beamline. The cryomagnet could be rotated so that the direction of applied magnetic field was either approximately parallel, or approximately perpendicular to the neutron beam. For SANS measurements on the polycrystalline samples, the magnetic field was applied perpendicular to the neutron beam (Fig. 1d,e), while measurements on the single crystal samples made use of an applied field approximately parallel to the neutron beam (Fig. 4b,c).

For either experimental geometry, the SANS measurements were done typically by rotating the sample and cryomagnet ensemble in a step-wise manner around its vertical axis—a so-called rocking scan—and over a sufficiently broad angular range, so as to move the various magnetic diffraction spots from the Bragg condition at the detector. Typical rocking scans spanned an angular range of up to ±20° with a SANS measurement conducted every 2°. This chosen step size was larger than the calculated instrumental contribution to the rocking half-width of the magnetic Bragg peaks (~0.2°), yet smaller than the observed Lorentz factor-corrected rocking half-widths, which, while sample dependent, were always >~4.5°. This observation demonstrates the observed rocking widths of the magnetic peaks to be dominated by the mosaicity of the magnetic order in the sample. By summing the detector measurements taken over all rotation angles, all of the diffraction spots can be seen in a single image, thus resulting in the SANS diffraction patterns shown in Figs 1 and 4.

**Discussion**

The present observation of skyrmions in this β-Mn-type chiral magnet demonstrates the long-held expectation that new skyrmion hosting systems can be found in a variety of non-centrosymmetric crystal symmetries, and may as such stimulate experimental exploration of other realizations, including other β-Mn structured materials. Likewise, the long sought-after demonstration of skyrmion stabilization above room temperature implies that complicated cooling is no longer a limiting factor for the potential integration of skyrmions into technological spintronics devices and applications.

**Methods**

**Sample preparation.** Polycrystalline samples of Co$_8$Zn$_{10}$Mn$_2$ (x + y + z = 20) were synthesized by the method described in ref. 29. Stoichiometric amounts of pure Co, Zn and Mn pieces of 2 g total mass were sealed in evacuated quartz tubes (~10$^{-3}$ Pa), heated to 1,000 °C for 12 h, followed by slow cooling (1 °C h$^{-1}$) down to 925 °C, then kept at this temperature for 75–100 h. Finally, the products were water quenched. A polycrystalline sample of Co$_8$Zn$_{10}$Mn$_2$ with larger grain sizes (typically up to 3 mm) was grown by the Bridgman method with cooling from 1,025 °C to ~700 °C over 1 week, followed by water quench. A single-crystal specimen was cut out from the resultant product and oriented with use of back-reflection X-ray Laue photographs.

Magnetic measurements. Magnetization and a.c.-susceptibility were measured by a superconducting quantum interference device magnetometer.

**Detection of the SKX formation in the bulk form.** To confirm the formation of the SKX in the bulk form more directly, SANS measurements were performed on a single-crystalline piece of Co$_8$Zn$_{10}$Mn$_2$ cut out from a polycrystalline ingot with fairly large grains obtained by the Bridgman method. Figure 4a shows the temperature dependence of the a.c.-susceptibility versus magnetic field along the [110] direction. We conducted SANS measurements in the configuration where the directions of incident neutron beam and magnetic field were both approximately along the [110] direction. As shown in Fig. 4b, a ring-shaped intensity distribution can be seen at $T = 317$ K and $H = 0$, suggesting the formation of multi-domain single q-helical structures with relatively flexible q-directions. At $H = 150$ Oe, which is inside of the dip anomaly of a.c.-susceptibility (see Fig. 4a), a six-fold-symmetric SANS pattern with magnetic reflections at $q = 0.0058$ Å$^{-1}$ can be clearly observed (Fig. 4c), thereby directly demonstrating the formation of the triple q-state or SKX with the lattice constant of $a_{SKX} = \sqrt[3]{\lambda} = \frac{4\pi}{\sqrt{3}q} \approx 125$ nm.

We thank A. Kikkawa for the help in sample preparation. This work was supported by JSPS Grant-in-Aids for Scientific Research (S) No.24224009 and for Young Scientists (A) (No. 25707032). Neutron scattering was performed at the Swiss Spallation Neutron Source (SINQ). Work in Switzerland was supported by the Swiss National Science foundation and the European Research Council project CONQUEST. H.M.R. gratefully thanks CEMS for the hospitality during this work.

**Author contributions**

The sample preparation and magnetic characterization were performed by Y. Tokunaga. UTEM observations were performed by X.Z.Y. CBED patterns were obtained and analysed by D.M. Small-angle neutron scattering measurements were conducted by J.S.W., H.M.R. and Y. Tokunaga. The results were discussed and interpreted by all the authors.
