Anatase TiO\textsubscript{2} Nanoparticles with Exposed {001} Facets for Efficient Dye-Sensitized Solar Cells

Liang Chu\textsuperscript{1}, Zhengfei Qin\textsuperscript{2}, Jianping Yang\textsuperscript{1} & Xing’ao Li\textsuperscript{2}

Anatase TiO\textsubscript{2} nanoparticles with exposed [001] facets were synthesized from Ti powder via a sequential hydrothermal reaction process. At the first-step hydrothermal reaction, H-titanate nanowires were obtained in NaOH solution with Ti powder, and at second-step hydrothermal reaction, anatase TiO\textsubscript{2} nanoparticles with exposed [001] facets were formed in NH\textsubscript{4}F solution. If the second-step hydrothermal reaction was carried out in pure water, the H-titanate nanowires were decomposed into random shape anatase-TiO\textsubscript{2} nanostructures, as well as few impurity of H\textsubscript{2}Ti\textsubscript{8}O\textsubscript{17} phase and rutile TiO\textsubscript{2} phase. Then, the as-prepared TiO\textsubscript{2} nanostructures synthesized in NH\textsubscript{4}F solution and pure water were applied to the photoanodes of dye-sensitized solar cells (DSSCs), which exhibited power conversion efficiency (PCE) of 7.06% (\textit{V}\textsubscript{OC} of 0.756 V, \textit{J}\textsubscript{SC} of 14.80 mA/cm\textsuperscript{2}, FF of 0.631) and 3.47% (\textit{V}\textsubscript{OC} of 0.764 V, \textit{J}\textsubscript{SC} of 6.86 mA/cm\textsuperscript{2}, FF of 0.662), respectively. The outstanding performance of DSSCs based on anatase TiO\textsubscript{2} nanoparticles with exposed [001] facets was attributed to the high activity and large special surface area for excellent capacity of dye adsorption.

Dye-sensitized solar cells (DSSCs), since the first report by Grätzel in 1991, have captured a lot of attentions due to the advantages of high power conversion efficiency (PCE), low cost, friendly to the environment, and simple fabrication process\textsuperscript{1–3}. Traditionally, standard DSSC structure is the combination of photoanodes, dye sensitizers, redox electrolytes, and counter electrodes\textsuperscript{4–6}. There, the photoanodes strongly affect the performance of DSSCs, which serve as scaffolds for dye molecules and the transport media for photo-generated electrons\textsuperscript{7–10}. As a result, considerable efforts have been devoted to pursuing a more effective photoanode.

Titanium dioxide (TiO\textsubscript{2}) is the shared material for photoanode in DSSCs, because of the high chemical and optical stability, low toxicity, and appropriate band structure\textsuperscript{11–13}. In DSSCs, the performance profoundly depends upon the morphology, crystalline phase, structure and exposed crystal facet of TiO\textsubscript{2}\textsuperscript{14–18}. The previous studies indicated that anatase TiO\textsubscript{2} single crystal with exposed [001] facets has good potency for dye adsorption and charge transfer\textsuperscript{17}. Both theoretical and experimental studies showed that [001] facets of anatase TiO\textsubscript{2} single crystal are extraordinarily reactive\textsuperscript{18}, and the surface energy is 0.90 J/m\textsuperscript{2}, which is much larger than 0.44 J/m\textsuperscript{2} surface energy of the usual [101] facets\textsuperscript{19}. To date, there have been a large number of reports for preparing anatase TiO\textsubscript{2} single crystal with appropriately exposed [001] facets for application of enhanced DSSCs, such as TiO\textsubscript{2} nanotube\textsuperscript{20}, anatase TiO\textsubscript{2} nanosheets\textsuperscript{21}, yolk@shell anatase TiO\textsubscript{2} hierarchial microspheres\textsuperscript{22}, and mesoporous TiO\textsubscript{2} single crystals\textsuperscript{8}. Yet it was reported that the ratio of [001] and [101] facet has impact on the performance of nanodevice because of the “surface heterojunction” of [001] and [101] surfaces, where appropriate but not great proportion of [001] facets is beneficial to the transfer and separation of photogenerated electrons and holes\textsuperscript{23,24}.

Nowadays, the efficiency of DSSCs has been achieved 13% through the molecular engineering of porphyrin sensitizers. It’s worth noting that the photoanode is TiO$_2$ nanoparticle film because of the large specific surface area for loading dye molecules. To the best of our knowledge, it is a challenge to synthesize TiO$_2$ nanoparticles with appropriately exposed {001} facets, which is the desired material for photoanodes of DSSCs. In this work, anatase TiO$_2$ nanoparticles with 34% exposed {001} facets were synthesized via a two-step hydrothermal reaction method from Ti powder, which were further developed as efficient photoanodes for DSSCs. The first-step hydrothermal reaction of Ti powder in NaOH solution led to the formation of H-titanate nanowires after washing with HCl solution, and the second-step hydrothermal reaction resulted in the formation of anatase TiO$_2$ nanoparticles with exposed {001} facets in NH$_4$F solution or random shape TiO$_2$ nanostuctures with tiny impurity phase in pure water. Subsequently, the obtained TiO$_2$ nanostructures were utilized as photoanodes of DSSCs, yielding PCE of 7.06% ($V_{OC}$ of 0.756 V, $J_{SC}$ of 14.80 mA/cm$^2$, FF of 0.631) and 3.47% ($V_{OC}$ of 0.764 V, $J_{SC}$ of 6.86 mA/cm$^2$, FF of 0.662), respectively. The result indicated the anatase TiO$_2$ nanoparticles with 34% exposed {001} facets possess the characteristics of high activity and large special surface area for the excellent capacity to load dye molecules.

**Results**

**Structure of anatase TiO$_2$ nanoparticles.** Figure 1(a) shows the powder XRD patterns of the as-grown H-titanate nanowires (I), as well as the obtained TiO$_2$ nanostructures synthesized in pure water (II) and in NH$_4$F solution (III). In curve (I), there are several broadened diffraction peaks, which correspond well to the H$_2$Ti$_5$O$_{11}$·H$_2$O phase (PCPDFWIN, 44-0130). Thus, the Ti powder was reacted with NaOH solution, after washing with dilute HCl solution, the obtained sample was H$_2$Ti$_5$O$_{11}$·H$_2$O. Taking the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires as precursor in the following hydrothermal treatment in pure water, the obtained powder was mainly indexed as anatase TiO$_2$ phase, as revealed in curve (II). Meanwhile, the another peaks besides anatase TiO$_2$ phase indicate that the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires were not completely decomposed into pure anatase TiO$_2$ phase. The peaks located at 27.71°and 41.86° were corresponded to (012) and (860) planes of H$_2$Ti$_8$O$_{17}$ phase, respectively (PCPDFWIN, 36-0656). While the peaks located at 36.13° and 56.55° were assigned to (101) and (220) planes of rutile TiO$_2$ phase (PCPDFWIN, 87-0710). More importantly, if the further hydrothermal reaction was taken in NH$_4$F solution, a pure phase of anatase TiO$_2$ (PCPDFWIN, 84-1286) was observed as the curve (III). Using the Scherrer equation, the average crystal size of anatase TiO$_2$ nanostructures obtained in NH$_4$F solution was about 45 nm estimated from the full width at half maximum of the (101) peak. Since no other diffraction peaks belonging to impurities are observed, suggesting that all the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires were completely converted to anatase TiO$_2$ phase in NH$_4$F solution. The diffraction peaks of curve (III) are sharper than that of curve (II), indicating the better crystallization and larger crystallites due to the enhanced effect of F$^-$.

The obvious (004) diffraction peak of curve (III) suggests dominant crystal growth along the [001] direction, which is typical for anatase TiO$_2$ nanoparticles with exposed {001} facets. In order to quantitatively analyze the percentage of {001} facets, Raman spectroscopy was carried out as shown in Fig. 1(b). The peaks at 144, 394, 514, and 636 cm$^{-1}$ suggest the typical anatase TiO$_2$ phase, being consistent with the XRD results. The percentage of {001} facets was calculated as 34% by measuring the peak intensity ratio of the $E_g$ (at 144 cm$^{-1}$) and $A_{1g}$ (at 514 cm$^{-1}$) peaks.
Figure 2 shows typical scanning electron microscopy (SEM) images of the TiO$_2$ synthesized in pure water and in NH$_4$F solution. After hydrothermal reaction and washing with HCl solution, the morphology of the as-prepared H$_2$Ti$_5$O$_{11}$·H$_2$O was nanowire structure (Fig. 1S in Supplementary Information). After the further hydrothermal treatment at 200 °C for 48 h, the morphology of the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires undergone significant change. The H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires were decomposed into random shape TiO$_2$ nanostructures in pure water, as shown in Fig. 2 (a,b). There was complex morphology of nanorod, nanosphere, nanoellipsoid, irregular nanostructures, etc. Interestingly, the morphology of the TiO$_2$ obtained in NH$_4$F solution was regular nanoparticles with size of ~50 nm as illustrated in Fig. 2(c,d), in good agreement with the XRD measurement. The NH$_4$F as morphology controlling agent led the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires to completely decomposing into regular TiO$_2$ nanoparticles.

The transmission electron microscopy (TEM) was used to further characterize the crystal structure and morphology of H$_2$Ti$_5$O$_{11}$·H$_2$O and TiO$_2$ nanostructures in Figure 3. Fig. 3(a,b) shows the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowire sample. The lattice fringes with distances of 0.940 nm in the HRTEM image of Fig. 3(b) corresponded well with (200) plane of H$_2$Ti$_5$O$_{11}$·H$_2$O phase. Figure 3(c) shows TEM image of random shape TiO$_2$ nanostructures by the further hydrothermal reaction in pure water. The HRTEM image (Fig. 3(d)) corresponding the dark red-box area shows interplanar spacing of 0.352 nm, which matches well with (101) plane of anatase TiO$_2$. When the second-step hydrothermal reaction was taken in NH$_4$F solution, the H$_2$Ti$_5$O$_{11}$·H$_2$O nanowires were decomposed into regular TiO$_2$ nanoparticles (Fig. 3(e)). The HRTEM image corresponding the cyan-box area in Fig. 3(e) was revealed in Fig. 3(f), where the interplanar spacing of 0.192 and 0.237 nm corresponded to (200) and (004) planes of anatase TiO$_2$, respectively. In addition, the (004) plane indicated the anatase TiO$_2$ single crystal with exposed [001] facets, and the shape of anatase TiO$_2$ was truncated octahedron. Further, the {001} facets could be also observed through TEM technique (Fig. 2S in Supplementary Information).

**Growth mechanism.** Figure 4 illustrates the schematic of the preparation process of random shape TiO$_2$ nanostructures and truncated octahedron TiO$_2$ nanoparticles with exposed [001] facets via a two-step hydrothermal reaction process. At the first-step hydrothermal reaction, Ti powder reacted with NaOH to synthesize Na-titanate nanowires. Followed by washing with diluted HCl solution, the
Na-titanate nanowires were transformed into H-titanate nanowires via cation exchange reaction. At the second-step hydrothermal reaction, the H-titanate nanowires precursors was undergone completely change in aqueous solution with or without NH₄F. In this process, the H-titanate precursors experienced

Figure 3. TEM and HRTEM images of the as-prepared samples. (a,b) H-titanate nanowires, (c, d) random shape TiO₂ nanostructures obtained in pure water, (e,f) truncated octahedron TiO₂ nanoparticles obtained in NH₄F solution.
a dissolution and nucleation process during the hydrothermal treatment. In pure water, the dissolution occurred without any restraint, thus TiO₂ nanostructures with random shape distribution were obtained. Moreover, the nucleation was not thorough, and there was few H₂Ti₈O₁₇ phase and TiO₂ rutile phase. When the H-titanate precursors were performed dissolution and nucleation in NH₄F solution, single crystal anatase TiO₂ nanoparticles with exposed {001} facets were obtained. At the dissolution process, the existing of F⁻ ions could be bonded with Ti atom to reduce the surface energy of the {001} facets to lower than that of the {101} facets, resulting in exposing {001} facets during nucleation. Besides, F⁻ ions acted as morphology controlling agent to control the shape of TiO₂ nanostructures during nucleation, and the shape of TiO₂ nanoparticles was truncated octahedron, as shown in Fig. 4.

**Characterization of Photovoltaic Performance.** The obtained TiO₂ powders were mixed with some additive agents to make TiO₂ pastes, and then the TiO₂ pastes were coated on TiCl₄-treated FTO glasses by doctor-blading method to realize photoanodes after annealing. The thickness of the TiO₂ photoanodes was 13.5 μm (Fig. 3S in Supplementary Information). Figure 5(a) indicates the current density-voltage (I-V) curves of the DSSCs based on random shape TiO₂ nanostructures (noted “Without F⁻”) and truncated octahedron TiO₂ nanoparticles with 34% exposed {001} facets (noted “With F⁻”). Table 1 listed the corresponding detailed photovoltaic parameters, including the open-circuit voltage (Vₜₜ), short-circuit current density (Jₛₜ), fill factor (FF), and PEC. The larger PCE 7.06% of DSSCs (noted “With F⁻”) was mainly rooted in the Jₙₚ, which increased from 6.86 to 14.80 mA/cm². Generally, Jₙₚ can be approximated as following expression:

\[
Jₙₚ = e\etaₜₜ\etaₙₗ\etaₙₑ I₀
\]

where \(e\) is the elementary charge, \(\etaₜₜ\) is the light-harvesting efficiency related to the amount of adsorbed dye molecules and the light-scattering properties, \(\etaₙₗ\) is the charge-injection efficiency, \(\etaₙₑ\) is the charge-collection efficiency relied on competition between charge recombination and collection, and \(I₀\) is the light flux. Here, \(\etaₙₗ\) is suggested to be of the same value, because of the injection both from the TiO₂ material to N719 dye.

Electrochemical impedance spectroscopic (EIS) measurements were conducted in the dark under a bias of 0.75 V to evaluate the charge transfer and recombination as the Nyquist plots in Fig. 5(b). The radius of semicircle in Nyquist plots revealed the charge-transfer resistance (\(Rₜₜ\)) between TiO₂/dye/electrolyte interfaces. The slightly larger one based on the random shape TiO₂ nanostructures (Without F⁻) indicated a slow charge recombination at the TiO₂/dye/electrolyte interfaces. Namely, the electron lifetime in photoanodes based on the random shape TiO₂ nanostructures was slightly longer. Moreover, the electron lifetime (\(τ\)) was calculated using the following equation:

\[
τ = RₜₜC_u
\]

where \(C_u\) is the corresponding chemical capacitance. The corresponding values of \(Rₜₜ\) (243.3 and 237.1 Ω) and \(C_u\) (7.5534 × 10⁻⁴ and 7.1165 × 10⁻⁴ F) can be obtained by simulation using the Zview software. The

**Figure 4. Schematic illustration of the synthetic route of TiO₂.** In pure water, random shape anatase TiO₂ with few H₂Ti₈O₁₇ and rutile TiO₂ nanostructures were formed. While in the present of NH₄F, truncated octahedron TiO₂ nanoparticles with exposed {001} facets were obtained.
electron lifetime was 0.184 (Without NH4F) and 0.179 s (With F−) of DSSCs, respectively. Meanwhile, the open-voltage decay method was employed to further investigate the electron lifetime of the two cells, as shown in Fig. 5(c). From the open-voltage decay rate, the electron lifetime (τ) can be calculated by the following equation35,36:

$$\tau = \left(\frac{k_B T}{e}\right)^{-1} \left|\frac{dV_{oc}}{dt}\right|$$

where $k_B$ is the Boltzmann constant, and $T$ is room temperature. The calculated data of τ were plotted in Fig. 5(d). It was observed that the electron lifetime based on random shape TiO2 nanostructures was slightly longer than that based on TiO2 nanoparticles. The possible reason was that there were some nanorods and relatively large nanoparticles in random shape TiO2 nanostructures, which were in favour of charge transfer. Therefore, it dos no outstanding difference to the charge transfer, and the value of $\eta_{cc}$ of DSSCs (noted “Without NH4F”) was little larger than that one (noted “With NH4F”). In other words, the increasing of $J_{sc}$ at over twice was not from the factor of $\eta_{cc}$.

Table 1. Photovoltaic parameters of the DSSCs based on random shape TiO2 nanostructures (noted “Without F−”) and truncated octahedron TiO2 nanoparticles with exposed {001} facets (noted “With F−”).

| Samples   | $J_{sc}$ (mA/cm²) | $V_{oc}$ (V) | FF  | PCE  | Adsorbed dye (nmol/cm²) |
|-----------|-------------------|--------------|-----|------|-------------------------|
| Without F− | 6.86              | 0.764        | 0.662 | 3.47% | 32.6                    |
| With F−   | 14.80             | 0.756        | 0.631 | 7.06% | 122.9                   |

Dye-adsorbed films with a dimension of 0.9 cm² were used for estimating the adsorbed dye concentration.
It is well-known that the nanoparticle films have large special surface area to load more dye molecules\(^1\). Therefore, the special surface area was checked by Brunauer-Emmett-Teller (BET) data as shown in Fig. 6(a). The BET surface area was measured as 40.9 and 44.6 \(m^2/g\) for random shape TiO\(_2\) nanostructures and TiO\(_2\) nanoparticles, respectively. The special surface area of TiO\(_2\) nanoparticles was slightly bigger than that of the random shape TiO\(_2\) nanostructures. More importantly, exposing highly reactive \(\{001\}\) facets of TiO\(_2\) can enhance dye adsorption\(^1\).\(^7\). Thus, we investigated the amount of absorbed dye molecules to elucidate the factor of \(\eta_l\). The optical image of TiO\(_2\) and sensitized-TiO\(_2\) films on FTO substrates was shown as the inset in Fig. 6(b). The color of random shape TiO\(_2\) nanostructure films (i) was lutescent, while the color of TiO\(_2\) nanoparticle films (ii) was pure white. After being sensitized by N719 dye, the color of the sensitized-TiO\(_2\) films based on TiO\(_2\) nanoparticles (iv) was darker red than that of based on random shape TiO\(_2\) nanostructures (iii), indicating that the TiO\(_2\) nanoparticles with exposed \(\{001\}\) facets absorbed more dye molecules. The UV-vis absorbance measurements in Fig. 6(b) revealed the sensitized-TiO\(_2\) films based on TiO\(_2\) nanoparticles (iv) had a stronger visible absorption, because of more amount of loading dye molecules. The absorbed dye amounts were calculated from UV-vis absorbance measurements of the concentration desorbed N719 dye in NaOH solution by using Lambert-Beer's Law\(^37,38\). The absorbed dye amount of photoanodes based on TiO\(_2\) nanoparticles with exposed \(\{001\}\) facets was about four times than that of based on random shape TiO\(_2\) nanostructures, as listed in Table 1. The TiO\(_2\) nanoparticles with exposed \(\{001\}\) facets had excellent capacity for adsorption of dye molecules. As a consequence, anatase TiO\(_2\) nanoparticles with exposed \(\{001\}\) facets were efficient photoanodes for DSSCs.

Discussion

Anatase TiO\(_2\) nanoparticles with 34% exposed \(\{001\}\) facets have been successfully synthesized from Ti powder via a two-step hydrothermal reaction process. The first-step hydrothermal reaction was alkaline hydrothermal reaction to obtain H-titanate nanowires. At the second-step hydrothermal reaction, the H-titanate nanowires were decomposed into random shape anatase TiO\(_2\) nanostructures with few impurity in pure water or truncated octahedron anatase TiO\(_2\) nanoparticles with 34% exposed \(\{001\}\) facets in NH\(_4\)F solution. The DSSCs based on anatase TiO\(_2\) nanoparticles with 34% exposed \(\{001\}\) facets showed outstanding performance of efficiency 7.03%, which was about twice than that of based on random shape TiO\(_2\) nanostructures. The high performance was ascribed to that the anatase TiO\(_2\) nanoparticles with 34% exposed \(\{001\}\) facets own high activity and large special surface area for excellent capacity of absorbing dye molecules. We anticipate that the anatase TiO\(_2\) nanoparticles with 34% exposed \(\{001\}\) facets open up a promising avenue for efficient TiO\(_2\)-based photoelectric nanodevices.

Methods

Materials. Fuorinated tin oxide (FTO, \(~7\Omega/cm^2\) glasses were bought from Nippin Sheet Glass Co., Ltd. Sodium hydroxide (NaOH, 96.0%), titanium tetrachloride (TiCl\(_4\), 99.0%), ammonium fluoride (NH\(_4\)F, 96.0%), hydrochloric acid (HCl, 36%-38%wt), ethanol (99.7%) and acetone (99.5%) were purchased from Sinopharm Chemical Reagent Co. Ltd. Ruthenium 535-bisTBA (N719) was purchased from Solaronix. Guanidinium thiocyanate (GuSCN, 99.0%) was from Amresco. Titanium powder (Ti, 99.99%), lithium iodide (LiI, 99.999%), iodine (I\(_2\), 99.99%), 1-methyl-3-propylimidazolium iodide (PMII, 98%), 4-tert-butylpyridine (4-TBP, 96%) and tert-butyl alcohol (99.5%) were obtained from...
Aladdin. Acetonitrile (99.8%) and valeronitrile (99%) were from Alfa Aesar. All solvents and chemicals were reagent grade and were used without further purification.

**Synthesis of H-titanate nanowires.** Na-titanate nanowires were firstly synthesized by alkali hydrothermal reaction of Ti powder in NaOH solution. First, 70 mL of 10 M NaOH solution was obtained under magnetic stirring. Then 0.2 g Ti powder was added into the above NaOH solution and stirred for 10 minimums again. The final solution was transferred to a 100 mL Teflon-lined stainless steel autoclave and loaded into an oven. The temperature was set 210 °C for 48 hours and then cooled down to room temperature naturally. After the hydrothermal treatment, the obtained Na-titanate nanowires were completely washed with 0.1 M HCl solution to replace Na⁺ with H⁺. Subsequently, the H-titanate nanowires were washed with deionized water several times.

**Synthesis of anatase TiO₂ nanoparticles with exposed [001] facets.** The above total H-titanate nanowires were added into 100 mL Teflon-lined stainless steel autoclave containing 70 mL deionized water with or without adding 0.25 M NH₄F. Afterward, the autoclave was loaded into an oven at 200 °C for 48 hours and then cooled down to room temperature naturally. After the hydrothermal reaction, the obtained TiO₂ powders were collected from the solution, and washed with deionized water and ethanol for several times by centrifugation. Finally, the powders were dried at 80 °C over night. The obtained dry powder was anatase TiO₂ nanoparticles with exposed [001] facets in NH₄F solution or random shape TiO₂ nanostructures with few impurity in pure water.

**Preparation of TiO₂ photoanode.** 1 g TiO₂ powder was mixed evenly under magnetic stirring in a mixture of 0.2 mL acetic acid, 3.0 g terpineol, 0.5 g ethyl cellulose and some ethanol to form a slurry, the slurry was milled in a mortar for about 20 min, and then dispersed with ultrasonic for 10 min to prepare viscous white TiO₂ paste. The FTO glasses were washed with detergent and sonicated in deionized water, acetone and ethanol for 20 min, respectively. After dried under flowing argon gas, the cleaned FTO glasses were soaked into 0.04 M TiCl₄ solution at 70 °C for 30 min to form a compact TiO₂ layer, and then rinsed with deionized water and ethanol. The TiO₂ pastes were printed onto the TiCl₄-treated FTO glasses by doctor-blading method. Then the printed TiO₂ layers were annealed at 125 °C for 15 min, at 325 °C for 5 min, at 375 °C for 5 min, at 450 °C for 15 min, and then at 500 °C for 15 min in a muffle furnace. The annealed TiO₂ layers were immersed into 40 mM TiCl₄ solution at 70 °C for 30 min again, and after being rinsed with deionized water and ethanol, the films were sintered at 500 °C for 30 min in muffle furnace. After the temperature was cooled to about 80 °C, the TiO₂ photoanodes were immersed into 0.5 mM N719 dye in acetonitrile/tert-butanol (V:V/1:1), and kept for 16 h at room temperature. The sensitized TiO₂ photoanodes were washed with acetonitrile to remove the possible physically-adsorbed dye molecules.

**Fabrication of DSSCs.** The Pt counter electrodes were deposited by magnetron sputtering on cleaned FTO glasses. Sputtering was performed using a Pt (99.99% purity) target in an Ar ambient atmosphere at 100 W. For fabricating DSSCs, the Pt counter electrodes were buckled on the sensitized TiO₂ photoanodes, which were sealed using a 50 μm plastic sheet and the internal space was filled with a liquid electrolyte. The electrolyte was composed of 0.6 M PMII, 0.05 M LiI, 0.03 M I₂, 0.1 M GuSCN and 0.5 M 4-TBP in acetonitrile and valeronitrile (V:V/85:15). The active area of the solar cell was 0.15 cm² without a mask.

**Measurement.** The crystal structure and phase purity of the obtained powders were investigated using a powder X-ray diffractometer (XRD, PANalytical B.V., The Netherlands) with Cu-Kα (λ = 0.15418 nm) radiation. Raman measurement was carried out using a Raman spectroscopy (LABRAM HR800, France) with a 514.5 nm argon ion laser of 200 μm spot size for excitation. The size and morphology of the samples were recorded by field emission scanning electron microscopy (SEM, FEI NOVA NanoSEM 450). Transmission electron microscopy (TEM) and high-resolution TEM (HRTEM) images were performed by TEM (FEI Tecnai G² 20 UTwin) or aberration-corrected TEM (FEI Titan G² 60–300). The sample was prepared by drop casting ethanolic dispersion of tiny TiO₂ powder onto a carbon coated Cu grid. The Brunauer-Emmett-Teller (BET, V-Sorb 2800P) was carried out to measure the surface area of the samples. The current density-voltage (I-V) measurements, open-voltage decay measurements, and electrochemical impedance spectroscopy (EIS) measurements were performed by an Autolab electrochemical workstation (model AUT84315, The Netherlands). UV-Vis absorption spectrometry (UV-2550, Shimadzu) was employed to test the absorption spectra. The illumination intensity was AM 1.5G (100 mW/cm², calibrated with a Si photodiode) using a solar simulator (Newport, USA). The electrochemical impedance spectroscopy (EIS) measurements were scanned in dark condition at a bias of 0.75 V with an amplitude of 10 mV in a frequency range from 100 kHz to 0.1 Hz. For testing the adsorbed dye amount of the TiO₂ working electrodes, the sensitized TiO₂ samples desorbed the dye into 0.1 M NaOH solution. The measured absorption spectra were used to calculate the amount of the adsorbed dye amount, expressed in terms of moles of dye anchored per projected unit area of the photoanodes.

Acknowledgements
We acknowledge the financial support from the National Basic Research Program of China (2012CB933301, 2014CB648300), the Ministry of Education of China (No. IRT1148), the National Synergistic Innovation Center for Advanced Materials (SICAM), the Natural Science Foundation of Jiangsu Province of China (BM2012010), the Project Funded by the Priority Academic Program Development of Jiangsu Higher
Education Institutions (YX03001), and the National Natural Science Foundation of China (51172110, 51372119).

Author Contributions
L.C. carried out all experiments, devised the original concept, and wrote the draft of the manuscript; Z.F.Q. participated in discussion of results; J.P.Y. & X.A.L. discussed the interpretation of results and revised the manuscript. All authors discussed the results and participated in manuscript revision. J.P.Y. & X.A.L. are corresponding authors.
