(July 97)

Properties of low-dimensional spin-Peierls systems are described by using a one dimensional $S = \frac{1}{2}$ antiferromagnetic Heisenberg chain linearly coupled to a single phonon mode of wave vector $\pi$ (whose contribution is expected to be dominant). By exact diagonalizations of small rings with up to 24 sites supplemented by a finite size scaling analysis, static and dynamical properties are investigated. Numerical evidences are given for a spontaneous discrete symmetry breaking towards a spin gapped phase with a frozen lattice dimerization. Special emphasis is put on the comparative study of the two inorganic spin-Peierls compounds CuGeO$_3$ and NaV$_2$O$_5$ and the model parameters are determined from a fit of the experimental spin gaps. We predict that the spin-phonon coupling is 2 or 3 times larger in NaV$_2$O$_5$ than in CuGeO$_3$. Inelastic neutron scattering spectra are calculated and similar results are found in the single phonon mode approximation and in the model including a static dimerization. In particular, the magnon $S = 1$ branch is clearly separated from the continuum of triplet excitations by a finite gap.

I. INTRODUCTION

Recently, a renewed interest for one dimensional (1D) spin chains was created by the observation of spin-Peierls transitions in the inorganic compounds CuGeO$_3$ and $\alpha'$-NaV$_2$O$_5$. Below some critical temperature $T_{SP}$, the spin-Peierls phase is experimentally inferred from a rapid drop of the spin susceptibility. The low temperature phase is characterized by the opening of a spin gap $\Delta$ (see below) and the dimerization of the lattice along the chain direction as confirmed for example by X-rays diffraction in CuGeO$_3$ and NaV$_2$O$_5$ or by Na NMR experiments in NaV$_2$O$_5$.

In general, these compounds are well described above the transition temperature by a 1D frustrated antiferromagnetic (AF) Heisenberg chain. The nearest neighbor and next-nearest neighbor spin exchange integrals $J$ and $J'$ can be determined by a fit of the magnetic susceptibility $\chi$ at high temperatures. In fact the position of the maximum of the curve and more generally the magnetic properties only depend on the frustration ratio $\alpha = J'/J$.

Parameters such as $J = 160$ K and $\alpha = 0.36$ have been suggested for CuGeO$_3$. Further studies seem to confirm that the dimerization is large in this system and we shall take $\alpha = 0.36$ in the rest of the paper. For the novel NaV$_2$O$_5$ system $J = 440$ K and $\alpha \approx 0$ have been proposed in good agreement with Refs. and the zero temperature spin gap $\Delta$ has been determined by several means. Inelastic neutron scattering (INS) gives a direct measure of it. So far INS has been performed on single crystals of CuGeO$_3$ and powder NaV$_2$O$_5$ samples. Values of $\Delta \approx 2.1$ meV have been reported, respectively. Other more indirect methods like NMR can also provide a measure of the magnitude of the spin gap. $^{63}$Cu or $^{65}$Cu NMR have been performed on single crystals of CuGeO$_3$ and $^{23}$Na NMR on aligned polycrystals of NaV$_2$O$_5$. The local magnetic susceptibility is proportional to the NMR Knight shift and the spin gap is estimated by a fit of the temperature dependence of the local susceptibility below the transition temperature. A value of $\Delta \approx 8.4$ meV was found for NaV$_2$O$_5$. A third independent estimation of $\Delta$ can be obtained by a fit of the low temperature bulk magnetic susceptibility of single crystals measured for instance by a SQUID-magnetometer technique. Ref. reports a value of $\Delta \approx 7.3$ meV for NaV$_2$O$_5$.

The dimensionless ratio $\Delta/J$ is the crucial parameter needed in our theoretical analysis. Results for CuGeO$_3$ are now well established and the value of $\Delta/J = 0.151$ is often used in the literature. Nonetheless ratios such as $\Delta/J = 0.203$, $\Delta/J = 0.175$ or $\Delta/J = 0.193$ can be found for NaV$_2$O$_5$. Since this last estimation was obtained from experiments performed on single crystals we have thus decided to use it as a reference. In any case, the quite small differences between the previous experimental values are not relevant.

Theoretically, the spin dynamics of the 1D Heisenberg chain depends strongly on the frustration parameter $\alpha$. Indeed, for $\alpha > \alpha_c \approx 0.241$ a gap appears in the spin excitation spectrum. Therefore, we expect that the two previous spin-Peierls compounds will have quite different magnetic properties. CuGeO$_3$ is dominated by intrachain frustration. On the other hand, NaV$_2$O$_5$ will behave, at high temperatures, more closely to an unfrus-
treated Heisenberg chain and, at low temperatures, the small interchain frustration alone cannot be responsible for the opening of a spin gap. The coupling to the lattice is therefore expected to play a dominant role in the transition at least for NaV$_2$O$_5$. In order to study their interplay, the frustration and the spin-lattice coupling have to be treated on equal footings. This is the purpose of this paper.

It is well known that a 1D system shows no phase transition at finite temperature because of quantum fluctuations. Interchain couplings are necessary to obtain a finite transition temperature. However, they are thought to be small and will be neglected hereafter in the study of zero temperature properties.

So far, there have been various attempts to treat the coupling to the lattice by considering a static dimerization $\delta$ of the exchange integral (so called adiabatic approximation or frozen phonon approximation). The value of $\delta$ is determined in order to obtain the experimental value of the zero temperature spin gap $\Delta$. Dimerizations such as $\delta = 0.014$ [8] and $\delta = 0.048$ [17] were proposed for CuGeO$_3$ and for NaV$_2$O$_5$, respectively, in order to reproduce the measured spin gaps (assuming $\Delta \approx 0.151J$ and $\Delta \approx 0.193J$ for CuGeO$_3$ and NaV$_2$O$_5$, respectively). Calculations using this approach have been performed in order to make first comparisons with experiments [15,20].

In this paper we use a modification of the previous static model to describe the physical properties of one-dimensional spin-Peierls compounds below the transition temperature. For convenience, the previous ad hoc static dimerization discussed above is replaced here by a single dynamical optical phonon mode (Section II). As far as thermodynamic properties are concerned, this model should be, in fact, equivalent in the thermodynamic limit to a model where the lattice is treated at a mean field level [21]. However, this new approach has some advantages: (i) it incorporates automatically the elastic energy and avoids the lengthy iterative procedure needed in a mean-field treatment to converge to the equilibrium static lattice dimerization; (ii) it enables to study the mechanism of the lattice symmetry breaking and, hence, provides a basis for future studies including a macroscopic number of phonon modes (i.e. proportional to the system length $L$) [22] in spin-Peierls chains.

Within this single mode approximation, we truncate the Hilbert space of the phonons and show in details that this approximation is well controlled (Section III). Using a finite size scaling analysis (discussed in detail in Section IV) the dimerization and the spin gap resulting from a spontaneous discrete symmetry breaking of the lattice periodicity are calculated (Section V). Focussing primarily on CuGeO$_3$ and NaV$_2$O$_5$ materials, we then establish a simple relation between the parameters of the model in such a way to enforce the constraint that the numerically calculated spin gap is equal to the experimental gap. The role of the parameters is discussed.

In the last part (Section VI), we study the spin dynamics. In particular, we investigate the role of the lattice dynamics on the low energy magnon branch and low energy structures in the dynamical spin structure factor. Our results are compared to the ones obtained in the static model [17,19,23,24].

II. MODELS

Our starting point is the 1D frustrated AF Heisenberg chain. For practical applications, the previous values of $J$ and $\alpha$ will be used: $J = 160K$, $\alpha = 0.36$ for CuGeO$_3$ [8] and $J = 440K$, $\alpha = 0$ for NaV$_2$O$_5$ [3]. In addition, a coupling between spins and dispersionless optical phonons (magneto-elastic coupling) is considered. For sake of simplicity we assume a linear dependence of the exchange integrals on the relative atomic displacements $\{u_i\}$ [23,24].

$$H = J \sum_i \left( (1 + \lambda u_i) \vec{S}_i \cdot \vec{S}_{i+1} + \alpha \vec{S}_i \cdot \vec{S}_{i+2} \right) + H^0_{ph},$$

(1)

where $\lambda$ is the coupling constant. $H^0_{ph}$ is the phononic Hamiltonian of identical independent quantum oscillators, $H^0_{ph} = \sum_i (\frac{p_i^2}{2m} + \frac{1}{2}K u_i^2)$ ($p_i$ is the conjugate momentum associated to the atomic displacement $u_i$). The atomic displacements $u_i$ and their conjugate variables can easily be expressed in term of the canonical phonon creation and annihilation operators $b^\dagger_i$ and $b_i$. Since the spin susceptibility diverges (for $\alpha < 0.5$ [27,28]) at momentum $k = \pi$ we expect that the coupling to the lattice will be dominant at $k = \pi$ which corresponds, in fact, to the modulation of the spin-Peierls ground state. Therefore, from now on, we shall only keep a single $k = \pi$ phonon mode [23]. In this case, using,

$$u_i \simeq (-1)^i \sqrt{\frac{1}{2mL\Omega}} (b_\pi + b_\pi^\dagger) \biggl( \Omega^2 = K/m \text{ and } L \text{ is the number of sites} \biggr),$$

the final Hamiltonian becomes,

$$H = J \sum_i \left\{ (1 + \frac{g(-1)^i}{\sqrt{L}} (b_\pi + b_\pi^\dagger)) \vec{S}_i \cdot \vec{S}_{i+1} + \alpha \vec{S}_i \cdot \vec{S}_{i+2} \right\} + H^0_{ph},$$

(2)

where $g = \sqrt{\frac{\lambda}{2mL\Omega}}$ is the dimensionless coupling constant. Within this approximation $H^0_{ph}$ can be rewritten as $H^0_{ph} = \Omega (b_\pi^\dagger b_\pi + \frac{1}{2})$ where $\Omega$ is the energy of a phononic quantum.

Before going further, we can already discuss qualitatively the physics contained in Hamiltonian (2). Indeed, we expect in the thermodynamic limit a discrete symmetry breaking corresponding to a doubling of the unit-cell. This can be described very simply at the MF level. By assuming a dimerization $\delta$ given by the order parameter...
where the last term is the elastic energy loss. This is exactly the well known model describing a static dimerization below the transition temperature in spin-Peierls systems [3,8]. Interestingly enough, a similar effective model has also been used to describe conjugated hydrocarbons with bond alternation such as polycetylene [30]. In this new form, the breaking of the lattice periodicity is explicit. As a consequence the ground state becomes doubly degenerate (the order parameter \( \delta \) can take a positive or a negative value) and a spin gap appears. The spin-Peierls ground state is characterized by a “…\( A-B-A-B \)…” pattern with a succession of strong singlet A bonds and weak singlet B bonds (so called Valence Bond or dimer state). Note that \( \delta \) in model (3) is a variational parameter to be determined in order to minimize the ground state energy by an iterative procedure. In contrast, the dimerization in Hamiltonian (2) arises from a dynamical symmetry breaking. However, it is interesting to notice that models (2) and (3) should be in fact equivalent [31] in the thermodynamic limit, at least as far as their thermodynamic properties are concerned [21,32].

Static and dynamical quantities are given by exact diagonalizations of small chains. Using a finite size scaling analysis, results in the thermodynamic limit are deduced. The parameters \( \delta \) on one hand and \( g \) and \( \Omega/J \) on the other hand are determined from a fit to the experimental spin gap.

III. TRUNCATION PROCEDURE

Let us now deal first with the numerical treatment of Hamiltonian (2). The total Hilbert space can be written as the tensorial product of the space of the spin configurations (to which the symmetry group of the problem is applied) times the phononic space. However, strictly speaking, the Hilbert space associated to the phonons is infinite even for a chain of finite length. Indeed, the natural basis \( \{ |n \rangle \} \) is simply defined by the unlimited occupation number \( n \) of the \( k = \pi \) phonon mode, \( |n \rangle = 1/\sqrt{n!} (b^\dagger)^n |0 \rangle \). Such a difficulty can nevertheless be easily handled in an exact diagonalization treatment [32]. The solution is to truncate the phononic space so that the occupation number is smaller than a fixed \( N_{\text{max}} \) which has to be chosen in an appropriate way. Clearly, if \( N_{\text{max}} \) is, let us say, an order of magnitude larger than the exact mean occupation number \( \langle b^\dagger b \rangle \) the truncation procedure will not affect the accuracy of the results which can then be considered as basically exact. This can be seen in Fig. 1 showing the energy per site of the ground state in the spin 0 and 1 sectors (the value of \( \alpha \) corresponds to the case of \( \text{CuGeO}_3 \) and a coupling constant \( g = 0.5 \) is used) for chains of length \( L = 12 \) and 20 plotted as a function of \( N_{\text{max}} \). Typically, the mean occupation number is smaller than 3 as in Figs. 2 and 3 (and in fact even smaller than \( \sim 0.5 \) for more realistic parameters) and the energy has converged for \( N_{\text{max}} \sim 30 \). Fig. 1 proves that the truncation procedure is very well controlled even for rather (unphysically) large coupling constants like \( g = 0.5 \). The results reported in the rest of this paper are then obtained with a sufficiently large value of \( N_{\text{max}} \) and the preliminary studies of the convergence of the results with increasing \( N_{\text{max}} \), although not mentioned each time, have been performed for each choice of the parameters of the model.

It is interesting to study the dependence of the mean occupation number on the three parameters of the problem (length of the chain \( L \), coupling constant \( g \) and frequency of the phonons \( \Omega \)) since, first, this number directly determines the practical value of \( N_{\text{max}} \) to be chosen and, secondly, it provides some physical understanding. Fig. 1 already suggests that the mean occupation number increases with the length of the chains. To investigate this effect in more details, the mean occupation number \( \langle \Psi_0 | b^\dagger_b | \Psi_0 \rangle \) in the ground state \( | \Psi_0 \rangle \) is plotted in Fig. 2 as a function of \( L \). Clearly, \( \langle \Psi_0 | b^\dagger_b | \Psi_0 \rangle \) (as well as the value required for \( N_{\text{max}} \)) grows linearly with the chain length \( L \). In fact, this effect is directly connected to the breaking of the lattice symmetry as can be seen very easily from a very simplified version of Hamiltonian (2). In a symmetry broken state, an effective (approximate) phononic Hamiltonian \( H_{\text{ph}} \) can be constructed by taking MF values for the spin operators. Assuming that \( \sum_{i} (-1)^i \langle \hat{S}_i, \hat{S}_{i+1} \rangle \) (dimer order parameter) varies linearly with \( L \) one then gets \( H_{\text{ph}} = A g \sqrt{\langle \hat{L} \rangle} (b_\pi + b^\dagger_\pi) + \Omega b^\dagger_\pi b_\pi \).
\(A\) is an undetermined constant. In this approximation, \(\langle b^\dagger_\pi b_\pi \rangle = A^2 g^2 L/\Omega^2\) grows linearly with the length of the chain. In addition, this simple argument also suggests that the occupation number of the \(\pi\) mode scales like the square of the dimensionless coupling \(g\) and like the inverse square of the phonon frequency. These intuitive behaviors are indeed well followed as can be seen in Fig. 3 in a large range of parameters.

IV. FINITE SIZE SCALING ANALYSIS

Firstly, we focus on the size dependence of the energy per site of the singlet ground state and of the lowest triplet state which are expected to converge to the same value in the thermodynamic limit. Typically, we use chains of length \(L = 8, 12, 16, 20\) and \(24\) sites. Data are shown in Fig. 4 for \(\alpha = 0.15, g = 0.45\) and \(\Omega = 0.3J\). The ground state energy per site varies roughly like \(1/L^2\). This behavior is predicted for gapless 1D chains obeying conformal invariance \([34]\) but seems to be still valid here in spite of the presence of a spin gap (see later). This already suggests that, for such parameters, the system sizes are still comparable to the spin correlation length but not much larger. The behavior of the triplet energy is more involved. An approximate \(1/L\) dependence is expected (giving a square root singularity in the \(1/L^2\) units of Fig. 4) if there is a finite spin gap \(\Delta\) (defined by the \(L \to \infty\) extrapolation of the difference \(\Delta(L) = E_0(S = 1, L) - E_0(S = 0, L)\) of the total energies of the lowest states of the singlet and triplet spin sectors). Such a behavior seems indeed to be observed in Fig. 4.

Let us now examine in details the behavior of the spin gap \(\Delta(L)\) versus \(L\) to extract values in the thermodynamic limit. Requiring that the extrapolated ratio \(\Delta/J\) of the model (2) is equal to the observed experimental value will lead to some constraint on the model parameters \(\Omega\) and \(g\). Our procedure can be summarised in three steps; (i) a controlled truncation procedure of the phononic Hilbert space for a large set of parameters \(g\), \(\Omega\) and system sizes \(L\), (ii) a finite size scaling analysis formed to obtain extrapolations to the thermodynamic limit.
in order to accurately determine the spin gap as a function of \( g \) and \( \Omega \); (iii) a determination of the relation to be followed by the parameters \( g \) and \( \Omega \) in order that the calculated ratio \( \Delta/J \) equals the actual experimental ratio (see Section III).

We first consider the scaling behavior of the spin gap. We have found that it scales accurately according to the law, 

\[
\Delta(L) = \Delta + \frac{A}{L} \exp\left(-\frac{L}{L_0}\right),
\]

where \( L_0 \) is a typical length scale. In general \( L_0 \) is of the order of the magnetic correlation length characterizing the decay of the equal time spin-spin correlation in real space. As seen later, values of \( L_0 \) are typically 20 lattice units (l.u.) for parameters corresponding to CuGeO\(_3\) and 30 l.u. for NaV\(_2\)O\(_5\). Therefore, with chains lengths up to 24 sites, finite size effects are still important and an accurate extrapolation is necessary. This scaling is illustrated for \( \alpha = 0.15 < \alpha_c \), \( g = 0.22 \), \( \Omega = 0.3J \) (\( \bigcirc \)), for \( \alpha = 0.36 > \alpha_c \) (CuGeO\(_3\)-like case), \( g = 0.089 \), \( \Omega = 0.3J \) (\( \square \)) and for \( \alpha = 0 \) (NaV\(_2\)O\(_5\)-like case), \( g = 0.40 \), \( \Omega = 0.5J \) (\( \bigotimes \)) in Fig. 5(a). A spin gap opens for all \( \alpha \) if \( g > 0 \). This is similar to the mean-field treatment where the order parameter \( \delta \neq 0 \) leads to the symmetry breaking and thus to the opening of a spin gap.

In Fig. 5(b) we compare, in the case of NaV\(_2\)O\(_5\) (i.e. \( \alpha = 0 \)), the scaling of the spin gaps calculated using the dynamical model \( \mathcal{M} \) with \( g = 0.275 \), \( \Omega = 0.3J \) (\( \bigcirc \)) on one hand and the static model \( \mathcal{S} \) with \( \delta = 0.05 \) (\( \square \)) on the other hand \( \mathcal{S} \). These values of the parameters have been chosen in order to obtain the same extrapolated spin gap. Although the spin gaps are equal, the two models exhibit slightly different scaling behaviors \((L_0 \approx 30)\) for the dynamical model and \( L_0 \approx 18 \) for the static one \( \mathcal{S} \).

At this stage, it is interesting to better understand how in the the dynamical model \( \mathcal{M} \) the opening of the spin gap is connected to the discrete symmetry breaking (as can be seen e.g. in X-rays scattering). The first signature of this phenomenon is the degeneracy of the ground state which is expected in the thermodynamic limit. We have therefore studied the behavior with system size of the energies \( E_p(S = 0) \), \( p = 0, 1, 2 \), of the three lowest singlet states. The energy differences \( E_1(S = 0) - E_0(S = 0) \) (circles) and \( E_2(S = 0) - E_0(S = 0) \) (squares) are plotted in Fig. 6 in the case \( \Omega = 0.3J \), as a function of the inverse length of the chain \( 1/L \) for \( \alpha = 0.36 \) (open symbols) and for \( \alpha = 0 \) (filled symbols). The values of the coupling \( g \) are chosen here in such a way to reproduce the experimental spin gaps of the CuGeO\(_3\) (open symbols) and NaV\(_2\)O\(_5\) (filled symbols) materials (see Section V). The results show very convincingly that the singlet ground state is indeed two-fold degenerate in the thermodynamic limit while a finite gap for singlet excitations appears above \( \Omega \). It is important to notice that the quantum numbers associated to the translation symmetry are different for the two lowest singlet states which correspond to momenta \( k = 0 \) and \( k = \pi \). Hence, mixing of these two states leads to a doubling of the unit cell.

The lattice dimerization can be quantitatively measured by the order parameter \( \delta^* = \frac{1}{\sqrt{2}}(b_\pi + b_\pi^\dagger)^{21/2} \) (the expectation value \( \langle b_\pi + b_\pi^\dagger \rangle \) vanishes because small tunnelling between the two degenerate dimer states always exists in a finite chain). \( \delta^* \) as a function of the inverse length of the chain is plotted in Fig. 7 for various pairs of parameters \( (\Omega, g) \) (see caption) chosen in such a way that the spin gap is constant (in fact adjusted to the actual spin gap of CuGeO\(_3\) as described in Section V). Extrapolated values of the dimerization \( \delta^* \) for different phonon frequencies are in fact quite close, at least in the range \( 0.1 \leq \Omega \leq 0.5 \). The dimerization \( \delta^* \) seems then to be only determined by the magnitude of the spin gap. The fact that \( \delta^* \), at fixed extrapolated spin gap, is independent of the frequency \( \Omega \) is consistent with the proof by Brandt and Lescile \( [21] \) that the thermodynamic properties of the dynamical model \( \mathcal{M} \) and of the static model \( \mathcal{S} \) are identical. However, it is interesting to notice that the value obtained here \(( \sim 0.022)\) is significantly larger than the value \(( \sim 0.014)\) needed in the MF approximation to produce the same gap. The differ-

\[ \Omega = 0 \]

\[ \Delta(\Omega) \]

\[ \alpha \]

\[ a \]

\[ J \]

\[ \text{for a large set of parameters } \Omega/J \text{ and } g. \]

\[ \text{For simplicity, let us first assume } \Omega/J = 0.3. \]

\[ \text{The behavior of } \Delta(\Omega/J = 0.3, g)/J \text{ versus } g \text{ is plotted in Fig. 8 for a large frustration } \alpha = 0.36 \text{ corresponding to the case of } \text{CuGeO}_3 (\circ) \text{ and for a non frustrated chain corresponding to the case of } \text{NaV}_2\text{O}_5 (\Box). \]

\[ \text{Quite generally, the spin gap grows with the coupling constant } g \text{ as expected. } \]

\[ \text{Indeed, a larger coupling to the lattice produces a larger dimerization and then, indirectly, a larger spin gap. } \]

\[ \text{The actual physical value of the ratio } \Omega/J \text{ is, to the best of our knowledge, difficult to obtain from experiment. Therefore, we shall not here restrict to any specific value of } \Omega/J \text{ but rather consider a wide range } 0.1 \leq \Omega/J \leq 0.5. \]

\[ \text{However, for each value of } \Omega, \text{ the dimensionless coupling constant } g(\Omega) \text{ can be determined by enforcing that the extrapolated spin gap ratio } \Delta(\Omega, g)/J \text{ equals the experimentally observed gap. } \]

\[ \text{The procedure is shown in Fig. 8 for } \Omega = 0.3J \text{ and } \alpha = 0 \text{ (NaV}_2\text{O}_5) \text{ and } \alpha = 0.36 \text{ (CuGeO}_3). \]

\[ \text{The small horizontal marks correspond to the actual experimental gaps, i.e. } \Delta/J \approx 0.151 \text{ and } \Delta/J \approx 0.193 \text{ for CuGeO}_3 \text{ and NaV}_2\text{O}_5, \text{ respectively. We then obtain } g(\Omega = 0.3) \approx 0.109 \text{ for CuGeO}_3 \text{ and } g(\Omega = 0.3) = 0.270 \text{ for NaV}_2\text{O}_5. \]

\[ \text{The same method was performed for two other values of the frequency, } \Omega = 0.1J \text{ and } \Omega = 0.5J. \]

\[ \text{A relation is then obtained between } \Omega \text{ and } g \text{ for the two values of the frustration parameter } \alpha = 0 \text{ and } \alpha = 0.36. \]

\[ \text{This is illustrated in Fig. 8. We find that } \Omega \text{ has to vary roughly like } g^2 \text{ in order that the spin gap is constant. Naively, one indeed expects that softer (i.e. with smaller } \Omega \text{) phonon modes are more effective to break the lattice symmetry. So, if one requires the spin gap to be constant, this effect has to be compensated by a smaller coupling } g. \]

\[ \Delta \]

\[ \Delta/J \]

\[ \text{FIG. 7. Order parameter } \delta^* \text{ as a function of the inverse of the length of the chain } 1/L \text{ for } \Omega = 0.1J \text{ and } g = 0.062 (\circ), \Omega = 0.3J \text{ and } g = 0.109 (\Box) \text{ and } \Omega = 0.5J \text{ and } g = 0.141 (\diamond) \text{ (see text regarding the choice of parameters).} \]

\[ \delta \]

\[ \Delta \]

\[ \Delta/J \]

\[ \text{FIG. 8. Spin gap } \Delta/J \text{ (in units of } J \text{) as a function of the magneto-elastic coupling } g \text{ for } \alpha = 0.36, \Omega = 0.3J (\circ) \text{ and } \alpha = 0, \Omega = 0.3J (\Box). \]

\[ \text{Vertical marks indicate actual experimental spin gap values.} \]

\[ \text{In Fig. 8 we observe that the coupling constant } g(\Omega) \text{ is roughly } 2.5 - 3 \text{ times smaller for CuGeO}_3 \text{ than for NaV}_2\text{O}_5 \text{ although the ratio of their spin gaps is only } 1.5. \]

\[ \text{This is an interesting consequence of the large frustration} \]

\[ \text{CuGeO}_3 \text{ and for a non frustrated chain corresponding to the case of } \text{NaV}_2\text{O}_5. \]
spin-phonon coupling. This effect is even more drastic in the static model \( (3) \) where the dimerizations \( \delta = 0.014 \) \( \text{(CuGeO}_3 \text{)} \) and \( \delta = 0.048 \) \( \text{(NaV}_2\text{O}_5 \text{)} \) have a ratio of about 4 \( ]17] \).

The model \( (3) \) seems to describe accurately the spin-Peierls transition. Theoretical parameters have been deduced from experiment and the ground state properties of the spin-Peierls phase have been established. We have provided evidences in favour of the dynamical breaking of the spin-Peierls phase have been obtained from experiment and the ground state properties \( S_\text{(CuGeO}_3 \text{)} \) of the Heisenberg chain in contrast to the case of CuGeO\(_3\) which exhibits a large frustration. The ratio \( \omega_{\text{max}}/J \) could therefore be considered as an additional accurate measure of the amount of frustration within the chain since the parameter \( \alpha \) alone determine approximately \( \omega_{\text{max}}/J \). It is interesting to notice also that, in the case of a frustrated chain (CuGeO\(_3\)), the upper limit of the continuum seems to be better defined.

At low energy, the dimerization gap leads to major differences with respect to the Heisenberg chain. First, there is no intensity for \( \omega < \Delta \). Secondly, the magnon branch is well separated from the continuum by a finite gap (see below) so that the magnon excitation can be interpreted as a spinon-spinon bound state \( [23] \). This bound state was also found in the static model \( (3) \) for CuGeO\(_3\) \([24,19]\) and NaV\(_2\)O\(_5\) \([17]\).

**FIG. 10.** \( S_{xx}(q, \omega) \) as a function of \( \omega/J \) calculated on a 20 site chain for \( q = n \pi/10, n = 0, \ldots, 10 \); \( a) \) CuGeO\(_3\) parameters, \( \alpha = 0.36, g = 0.109, \Omega = 0.3 J \); \( b) \) NaV\(_2\)O\(_5\) parameters, \( \alpha = 0, g = 0.270, \Omega = 0.3 J \). A broadening of the \( \delta \)-functions \( \epsilon = 0.04 J \) was used.

The dispersion relations of the magnon branch \( (\circ) \), the second excitation \( (\square) \) and the upper limit of the continuum \( (\diamond) \) in the dynamical model \( (3) \) are plotted in Fig. 11(a) for CuGeO\(_3\). The \( \diamond \) symbols correspond to experimental results from Ref. \([13]\) and filled symbols correspond to infinite size extrapolations at momenta \( q = \pi/2 \) and \( q = \pi \). Similar dispersion relations are shown in

### VI. DYNAMICAL PROPERTIES

INS is a powerful experiment probing the momentum-dependence of the spin dynamics. INS has been performed on CuGeO\(_3\) single crystals \([13,12]\) and on NaV\(_2\)O\(_5\) powders \([8]\). It provides a direct measure of the dynamical spin-spin structure factor,

\[
S_{xx}(q, \omega) = \sum_n |\langle \Psi_n | S_x(q) | \Psi_0 \rangle|^2 \delta(\omega - E_n + E_0),
\]

(5)

where \( | \Psi_0 \rangle \) is the (singlet) ground state of energy \( E_0 \) and the sum is performed on all triplet excited states \( | \Psi_n \rangle \) of energy \( E_n \). \( S_x(q) \) is normalised as \( 1/\sqrt{\sum_q \exp(\imath q j) S_z^2} \).

The INS spectrum can be easily computed by exact diagonalization techniques \([35]\). Results on a 20 site chain are shown in Fig. 11(a) for CuGeO\(_3\) and in Fig. 11(b) for NaV\(_2\)O\(_5\) with a frequency \( \Omega = 0.3J \). In both cases we observe a well defined q-dependent low energy structure as for the static model \( (3) \). Its bandwidth (i.e. the energy at the maximum of the dispersion at \( q = \pi/2 \)) is typically \( \omega_{\text{max}} \sim 1.1J \) for CuGeO\(_3\) and \( \omega_{\text{max}} \sim 1.6J \) for NaV\(_2\)O\(_5\). This second value is very close to the DesCloizeaux-Pearson value of \( \pi/2 \) \([38]\) of the Heisenberg chain in contrast to the case of CuGeO\(_3\) which exhibits a large frustration. The ratio \( \omega_{\text{max}}/J \) could therefore be considered as an additional accurate measure of the amount of frustration within the chain since the parameter \( \alpha \) alone determine approximately \( \omega_{\text{max}}/J \). It is interesting to notice also that, in the case of a frustrated chain (CuGeO\(_3\)), the upper limit of the continuum seems to be better defined.

At low energy, the dimerization gap leads to major differences with respect to the Heisenberg chain. First, there is no intensity for \( \omega < \Delta \). Secondly, the magnon branch is well separated from the continuum by a finite gap (see below) so that the magnon excitation can be interpreted as a spinon-spinon bound state \([23]\). This bound state was also found in the static model \( (3) \) for CuGeO\(_3\) \([24,19]\) and NaV\(_2\)O\(_5\) \([17]\).
Fig. 11(b) for NaV$_2$O$_5$ and the position of the experimental $q = \pi$ spin gap [3] is indicated by an arrow. Note that we have explicitly checked that the magnon branch is well separated from the continuum. A finite size scaling analysis of the energies of the two lowest triplet states (■) is indeed possible at momentum $q = \pi/2$. Figs. 11(a-b) clearly show that there is a finite gap between the first branch and the continuum as in the static model. It is consistent with the fact that the continuum corresponds to solitonic spin-$1/2$ excitations (or spinons) and that solitons and antisolitons can bind in pairs with momenta close to $q = \pi/2$ [23]. Such a double gap feature was indeed observed experimentally [39].

It is important to notice that the dispersion relation is not symmetric with respect to $q = \pi/2$ in contrast to the case of a static dimerization. In fact, such a symmetry in the energy spectrum is due to the Bragg scattering resulting from the doubling of the unit cell. Since the dimerization appears only as a true phase transition in the case of CuGeO$_3$, our results are in very good agreement with INS experiments although finite size effects are still important. In fact the agreement improves with increasing system size since the calculated magnon branch for $q > \pi/2$ shifts slightly to lower energy when $L$ grows (in order to be symmetric with the $q < \pi/2$ part). Note also that energy scales are four times larger for NaV$_2$O$_5$ than for CuGeO$_3$ which could restrict INS experiments on NaV$_2$O$_5$ to low energy regions of the spectrum in the vicinity of $q = \pi$.

It is interesting to compare results for the spin dynamics obtained within the dynamical model to the ones obtained within the static model. Fig. 12 shows the lowest triplet magnon branches and the next triplet excitations (in fact lower limits of the $S = 1$ continuum) for parameters suitable for CuGeO$_3$. We do not explicitly show the comparison of the upper limits of the continua since the two curves obtained within the two models are almost indistinguishable. This is not surprising because higher energy excitations are only determined by the magnitude of the frustration and the coupling to the lattice plays a minor role here. At lower energy, the magnon branches of the two models look also very similar for $q < \pi/2$ but some differences appear for $q > \pi/2$ since, as explained before, the dispersion is not symmetric with respect to $\pi/2$ in the dynamical model. This is simply due to larger finite size effects [10] occurring in model (2) related to the fact that the lattice periodicity is only spontaneously broken. Once such finite size effects are taken into account we can safely conclude that the dispersions of the magnon branches of the two models in the thermodynamic limit are very close. Similarly, the discrepancies seen between the positions of the lower limits of the continua of triplet excitations are not relevant. Indeed, a detailed finite size scaling analysis at e.g. $q = \pi/2$ reveals that the position of the two lower limits are in fact quite close (1.117$J$ for [1] to be compared to 1.118$J$ for [3]). An exactly similar

\[ S_{zz}(q) = \int d\omega S_{zz}(q, \omega) , \]

which can be obtained in INS by integrating the spectrum over energy is plotted in Fig. 13 for CuGeO$_3$ ($\alpha = 0.36$, $g = 0.109$, $\Omega = 0.3J$) (■) and NaV$_2$O$_5$ (●) ($\alpha = 0$, $g = 0.270$, $\Omega = 0.3J$) for a 20 site chain. It is peaked near $q = \pi$ as a result of strong short range AF correlations. Indeed the width of the peak at $q = \pi$ is directly related to the inverse magnetic correlation length. Note however that $S_{zz}(q)$ is slightly suppressed in CuGeO$_3$ compared to NaV$_2$O$_5$ because of the interchain frustration. In any case, the results are very similar to those obtained with the static dimerized model. The relative weights of the magnon peak in $S_{zz}(q, \omega)$ are also shown for CuGeO$_3$ (□) and NaV$_2$O$_5$ (■). Their behaviors versus $q$ suggest that working in a range of momenta around $q = 0.8\pi$ might be
VII. CONCLUSIONS

In order to describe one dimensional spin-Peierls compounds, a magneto-elastic (i.e. spin-phonon) coupling has been considered and is shown to be responsible for a dynamical and spontaneous breaking of the lattice periodicity followed simultaneously by the opening of a spin gap. The resulting symmetry-broken ground state is consistent with the existence of a frozen dimerization such as the one obtained in a mean-field treatment of the coupling to the lattice. We have used exact diagonalization techniques to calculate static and dynamical properties of this model. Controlled truncation procedures have been applied to the bosonic Hilbert space of the Hamiltonian. By using a finite size scaling analysis, we have compared various physical quantities to the experimental ones (in the case of CuGeO$_3$ and NaV$_2$O$_5$) and we have determined a range of suitable parameters for the model. We predict that the spin-phonon coupling is 2 or 3 times larger in NaV$_2$O$_5$ than in CuGeO$_3$. The INS spectrum calculated within this model is found to be qualitatively similar to the one obtained in the static model with a finite gap separating the magnon branch from the continuum of triplet excitations above.

D.A. acknowledges useful discussions with M. Albrecht and S. Capponi. We thank L. P. Regnault for communicating to us the data of Ref. [13], J. Riera for valuable comments and IDRIS (Orsay) for allocation of CPU time on the C94 and C98 CRAY supercomputers.

After completion of this work, we learnt of a related work by A. W. Sandvik et al. (cond-mat/9706046) using a Quantum Monte Carlo approach.
