Review of thin films of RFe_2O_4 (R=Lu, Yb, Tm or In)

Abstract

Rare earth ion ferrite RFe_2O_4 (R = Y, Dy, Ho, Er, Tm, Yb, Lu, Sc, or In) has been attracted much attention due to its anomalous physical properties as a candidate of electronic ferroelectric. Although most of reports were discussed by bulk sample, much effort has been made in fabricating film of RFe_2O_4 recently. Finally the charge order was directly observed just recently. Also some data indicate the spin-charge-orbital coupling. In this paper, the film growth and electric, magnetic and optical properties of the films are briefly reviewed.

Keywords: correlated electron system, electronic ferroelectric, film

Introduction

The strongly correlated electron system has been attracted much attention in solid state physics due to its abnormal electric, magnetic and optical properties which promises novel application. Rare earth ion ferrite RFe_2O_4 (R = Y, Dy, Ho, Er, Tm, Yb, Lu, Sc, or In) is the typical example. This material is composed of doubly stacked iron triangular layers (W-layer) separated by single rare-earth triangular layer. Equal amounts of Fe^{2+} and Fe^{3+} exist on triangular lattices and form charge orders due to the Coulombic interaction between iron ions. The charge ordered W-layers stack randomly and regularly above and below three-dimensional charge ordering temperature, respectively.

It has been proposed that each W-layer has microscopic electric spontaneous polarization, and the in-phase and out-of-phase stacking of the polar W-layers generate ferroelectric and antiferroelectric charge orderings respectively. Although the existence of the polar W-layer has been questioned recently, the macroscopic spontaneous polarization observed by P-E loop supports the existence of the polar W-layer. These novel ferroelectricity has been called “electronic ferroelectricity”, having great possibility for innovative devices. Since the polarization switching can be realized with only electron hopping and without lattice distortion, low-energy, high-speed and well-repeatable switching is expected. These hypotheses are supported by experimental results. The hopping energy of the electron from Fe^{2+} to Fe^{3+} is confirmed as 0.3 eV by Mossbauer experiments. The charge order can melt and reconstruct in pico seconds order according to the pump probe experiments. Furthermore, the melting of the charge order provokes non-linear electric conductivity which can be used as a switching device.

RFe_2O_4 also shows interesting magnetic property. Each W-layer also has the net magnetic moment due to the ordering of the spins on iron ions. The two kinds of stacking manner of the magnetic W-layers generate ferrimagnetism and antiferromagnetism in analogy with ferroelectricity and antiferroelectricity. Since both of the electric and magnetic properties arise from the ordering of iron ions, correlation is expected between electric and magnetic properties. Actually we have reported a magnetoelectric effect.

Most of these attractive properties were observed in bulk sample. The key for the application of RFe_2O_4 is the film growth. However, the film fabrication of this material is still a developing research due to the difficulty in selecting substrates and keeping the stoichiometry, which changes various properties significantly. 13 reports have been published by 2017, following the first report by M. Seki et al in 2010. In this paper, the film growth and electric, magnetic and optical properties of the films are briefly reviewed.

Fabrication of the film

Various trivalent ions are selected as R ion in reported films: Lu, Yb, Tm and In. The change in R ions is unlikely to affect intrinsically as well as for bulk. These films are fabricated on various substrates: Al_2O_3(001), MgAl_2O_4(111), ZnO(001), MgO(111), MgAl_2O_4(111), and 6H-SiC(001). Although the lattice mismatch is not small with all substrates, MgAl_2O_4 is likely to have the best lattice constant in these substrates. Clean interface is observed on MgAl_2O_4 substrate with MgAl_2O_4 [2-1-1]/LuFe_2O_4[100] without any impurity and disordered layers as shown in Figure 1.

*Figure 1* High angle annular dark field scanning transmission electron microscopy images of the LuFe_2O_4 film on MgAl_2O_4 substrate showing (a) the presence of a clean interface and (b) the well-ordered structure of LuFe_2O_4 layers alternating with Fe_2O_3 layers. An overlay of a single unit cell is shown in the lower corner of (b).

Also various deposition techniques are tried: pulsed laser deposition (PLD), electron beam deposition (EB), molecular beam epitaxy (MBE) and rf magnetron sputtering. The most popular way to fabricate RFe_2O_4 film is PLD. The ablation is performed on RFe_2O_4 target prepared by solid state reaction. The chamber pressure during the deposition differs depending on the groups: 10^3 Pa – 1 Pa. Although most of all substrates are heated up to 700°C – 900°C, too much heating often lead iron defects.
The as-depo films are annealed in some reports.\textsuperscript{1,2,3} Although each group tried optimization of the deposition condition and discussed the composition, crystal structure and morphology, the conclusion differs depending on the groups. EB realizes higher crystallized film, despite of poor orientation. $\text{RFe}_2\text{O}_4$ target is prepared by solid state reaction. The chamber pressure and substrate temperature are almost the same as those of PLD. As for MBE, iron and rare earth elemental fluxes are provided from different effusion cells. The deposition condition is simulated by calculation.\textsuperscript{23}

In these various deposition techniques, much effort has been made to get high stoichiometric film.\textsuperscript{1,2,3,23,24} The most popular way to overcome easier vaporization of Fe is deposition in Fe-rich environment: Fe enriched target or higher power of Fe source. Kashimoto R et al.\textsuperscript{27} suppressed revaporization of Fe ion by detail investigation of the emission intensity variation of each element with defocus degree, chamber pressure and substrate temperature.\textsuperscript{27} The substitution of Cu for a half amount of Fe is also effective to control the ratio of divalent ions to trivalent ions because Cu\textsuperscript{2+} and Fe\textsuperscript{3+} are stable.\textsuperscript{17} However, Fe-rich environment often generates Fe$_3$O$_4$ in initial growth.

Fujii T et al.\textsuperscript{23} utilized Fe$_3$O$_4$ as a buffer layer and succeeded in getting the highest crystallization by rf magnetron sputtering.\textsuperscript{23} The Fe$_3$O$_4$ was deposited on Al$_2$O$_3$ (0001) substrate at first, and then YbFe$_2$O$_4$ was fabricated on the Fe$_3$O$_4$ layer. They prepared two cathodes; one for pure Fe target and another for Yb target. The powers of the two cathodes were controlled separately. Figure 2 shows cross section transmission electron microscopy (TEM) image of the bilayer film and selected area electron diffraction (SAED). Clear superlattice diffraction spots are observed in the panel C, indicating the formation of the charge order with long coherence length. This is the only one report of the crystal in which the existence of the charge order is confirmed at present.

\end{figure}

\textbf{Magnetic property}

The intrinsic magnetic property is likely to be the same as that of bulk as reported in refs.\textsuperscript{20,25,26} Figure 3 shows the magnetization as a function of temperature and magnetic field.\textsuperscript{13} The most of the $M$--$H$ loop of the film show similar curve with Figure 3. Both of film and bulk samples often show hysteresis and large coercive field and saturation magnetization. The single and double hysteresis loops are observed in stoichiometric and off-stoichiometric samples, respectively.\textsuperscript{26} The peak in zero field cooling (ZFC) curve also indicates high crystallinity of the film on SiC substrate is indicated by the peak in ZFC curve and near single hysteresis loop in $M$--$H$ curve.\textsuperscript{21,23,24} The Neel temperature ($T_N$) is a little lower than that of the bulk, which likely to arise from lower crystallization or longer c-axis and shorter a- and b-axes by stress from the substrate. The coercive field is small in refs.\textsuperscript{20,25} due to size effect.

Seki M et al.\textsuperscript{27} reports magnetic memory effect.\textsuperscript{17} The memory in the cooling process is read in the heating process. The sample was cooled under the magnetic field from 200K to 4K with a rate of 10K. Then the magnetization showed clear jump at 10 K in the heating process as shown in Figure 4. Such memory effect is a step in research for application.

The solid black circles are measured during cooling in 50 Oe at a constant rate of 4K/ min with a stop of 4h duration at 10K. The field was switched off during a stop. The open red circles are measured with continuous heating at the same rate after the previous cooling procedure.\textsuperscript{17}}
\end{figure}

\textbf{Electric property}

The electric property is reported in refs.\textsuperscript{18, 19, 21, 24, 26} The intrinsic electric property is also likely to be the same as that of bulk. The resitivity significantly differs depending on the stoichiometry. $1 \text{\Omega cm} – 104 \text{\Omega cm}$ of the resistivity is reported at room temperature. The higher resitivity indicates higher stoichiometry. As for the temperature dependence, the electric property shows anomaly only at $T_c$ and three-dimensional charge-ordering temperature, $T_{CO}$.\textsuperscript{21,24,26} Figure 5 shows the temperature dependence of resistance of the film.\textsuperscript{17} The discontinuous change and kink are observed at $T_c$ and $T_{CO}$ in R-T curve respectively. The same sample shows significant peak at $T_{CO}$ in the loss term of dielectric constant. However the magnitude of the anomalies depends on the sample. The sample in ref.\textsuperscript{26} shows anomaly only at $T_c$ in R-T curve. The sample in ref.\textsuperscript{24} shows anomaly only at $T_{CO}$. Aside from the magnitude, these anomalies at $T_{CO}$ and $T_c$ indicate spin-charge coupling and the charge order as the key of the electric property. Although such anomalies are reported also in bulk, films show larger anomalies. It is important that the spin-charge coupling become prominent in film rather than be kept.

The dielectric property is reported in refs.\textsuperscript{18,23} The large dielectric constant is observed with gold electrodes while the intrinsic dielectric constant is small in bulk. The larger dielectric constant of the film may arise from high conductivity or off-stoichiometry which changes fermi level.\textsuperscript{23} Accompanied

by the change in the magnitude of the interface effect between the sample and gold electrodes. The dielectric tunability is also reported. Figure 6 shows the dielectric tunability of the film under the electric field and magnetic field. The dielectric constant decreases 35% under 5kV external electric field. Furthermore, the dielectric tunability can be changed by external magnetic field. These results also indicate the spin-charge coupling and great possibility for application.

**Figure 5** Temperature dependence of resistance of LuFe\(_2\)O\(_4\) film during heating.

![Figure 6](image.png)  
**Figure 6** Dielectric tunability of the LuFe\(_2\)O\(_4\) film measured at room temperature under the electric field and the magnetic field.

Huge nonlinear electric conductivity is reported in ref. Both of the intrinsic nonlinearity and Jule effect are likely to be detected. The nonlinear electric conductivity can be observed significantly in the film since the thin film can be applied much larger electric field than bulk. Hall effect is also reported. The p- and e-type conductivity are observed above and below 440K, respectively, indicating the film keeps the bulk property.

### Optical property

The films have advantage in research on the optical property than bulk. The optical property is reported in refs. Figure 7 shows representative absorption spectra of LuFe\(_2\)O\(_4\) film as a function of photon energy at 78 and 300K. The peaks are observed around 1.6 eV, 2.4 eV and 3.3 eV, corresponding to the Fe\(^{2+}\) d to d on-site transition and the O 2p to Fe 3d charge-transfer transition, estimated from first-principles electronic structure calculations. The band gap was estimated to 0.3 eV and 2.4–3.4 eV as indirect and direct gaps, respectively. The temperature dependence of the spectra is also discussed. The direct band gap became larger with decreasing temperature. The significant anomaly is observed in the band gap around \(T_{CO}\) and \(T_{N}\). Moreover, the absorption spectra of the charge transfer show sharp decline at \(T_{CO}\). Also clear differences are reported in optical spectra between below and above \(T_{CO}\) in ref. These results indicate strong spin-charge-orbital coupling. The anomaly is also observed around 180K, suggesting the structure distortion while the physics around 180K has been controversial topic in bulk.

Furthermore, refs. reported electro-optical effects. 9% of large electro-optical effects are reported under 500 V/cm of the electric field at 10K. The magnitude of the electro-optical effect increases with decreasing the temperature. Figure 8 shows the electro-optic signal at 78 and 170K. The electro-optical effects are 4+% ~ −5% at 78K, and +3.5 ~ −1.5% at 170K under 200 V/cm of the electric field. Above \(T_{CO}\), they observed very small (<1%) electro-optical effects. The large electro-optical effects below \(T_{CO}\) indicates a strong spin–charge coupling. The inset of Figure 8 shows the largest electro-optical signal as a function of applied voltage at 78K and 170K. Linear electro-optical effects are observed. The mechanism of the electro-optical effect in this material may be different from that in the perovskite-type ferroelectrics since the mechanism of the ferroelectricity is likely to be different. The research on the optical property will be more progressed by recent higher quality films.

**Figure 7** Representative absorption spectra of the LuFe\(_2\)O\(_4\) film on sapphire at 78 and 300K, extracted from the transmittance data. The arrows indicate the electronic transitions. The inset shows the Fe\(^{2+}\) (d) crystal-field splitting scheme. (b) The absorption peaks at 2.40 eV (Fe\(^{2+}\) d to d on-site) and 3.30 eV (O 2p to Fe 3d charge transfer) transitions as a function of temperature. The shaded vertical lines designate \(T_{N}\) and \(T_{CO}\).

![Figure 8](image.png)  
**Figure 8** Electro-optical effects in applied dc voltages up to 200V, and the absorption coefficient of the LFO thin film in the photon energy range of 1–2.75 eV at (a) 78K and (b) 170K. The absorption spectrum in (a) shows the Fe\(^{2+}\) d to d on-site electronic transitions at ~1.60 and 2.40 eV, respectively. The observed electro-optical effects are stronger around the rising slope of the 1.60 eV peak and vary from +4% to −5% at 78K, and from +3.5 to −1.5% at 170K, respectively. The inset in (b) shows the electro-optical signal as a function of applied voltage at 78 and 170K.

### Conclusion

Much effort has been made in fabricating film of \(RFeO_4\), which is the candidate of electronic ferroelectric. In this paper, the film growth and electric, magnetic and optical properties of the films are briefly reviewed. Although these research has short history, the charge order was directly observed just recently. Also some data indicate the spin-charge-orbital coupling. The research on the optical property progressed. Attractive properties for application are also reported. The spin-charge-orbital coupling and magnetic memory effect...
