ABSTRACT

Supernovae (SNe) with strong interactions with circumstellar material (CSM) are promising candidates sources of high-energy neutrinos and gamma rays, and have been suggested as an important contributor to Galactic cosmic rays beyond \(10^{15}\) eV. Taking into account the shock dissipation by a fast velocity component of SN ejecta, we present comprehensive calculations of the non-thermal emission from SNe powered by shock interactions with a dense wind or CSM. Remarkably, we consider electromagnetic cascades in the radiation zone and subsequent attenuation in the pre-shock CSM. A new time-dependent phenomenological prescription provided by this work enables us to calculate gamma-ray, hard X-ray, radio, and neutrino signals, which originate from cosmic rays accelerated by the diffusive shock acceleration mechanism. We apply our results to SN IIn 2010jl and SN Ibn 2014C, for which the model parameters can be determined from the multi-wavelength data. For SN 2010jl, the more promising case, by using the the latest \textit{Fermi} Large Area Telescope (LAT) Pass 8 data release, we derive new constraints on the cosmic-ray energy fraction, \(\epsilon_p \lesssim 0.05 - 0.1\). We also find that the late-time radio data of these interacting SNe are consistent with our model. Further multi-messenger and multi-wavelength observations of nearby interacting SNe should give us new insights into the diffusive shock acceleration in dense environments as well as pre-SN mass-loss mechanisms.

\textit{Keywords:} nonthermal, supernovae

1. INTRODUCTION

Supernovae (SNe) have been widely believed to be the main contributors to Galactic cosmic rays (CRs). The observed CR flux can be explained if \(\sim 10\%\) of the SN ejecta energy, \(\mathcal{E}_e \sim 10^{51}\) erg, is converted into the kinetic energy of accelerated CR ions. It has been believed that the diffusive shock acceleration (DSA) mechanism is responsible for particle acceleration in supernova remnants (SNRs) (see, e.g., Drury 1983, for a review), and SNRs have been observed in gamma rays with gamma-ray observatories such as \textit{Fermi} and imaging atmospheric Cherenkov telescopes (IACTs) such as H.E.S.S., MAGIC, and VERITAS. Recent detailed observations at sub-GeV energies have led to the discovery of a low-energy cutoff due to neutral pion decay, which is regarded as evidence of hadronic gamma-ray emission from \(\pi^0 \rightarrow 2\gamma\) (see Funk 2015, and references therein). Independent of these phenomenological and observational arguments, state-of-art particle-in-cell simulations have also revealed that CR ions carry \(\sim 10\%\) of the SN ejecta energy via the DSA mechanism (e.g., Caprioli 2016).

How early is high-energy non-thermal emission anticipated? Obviously, most of the SN explosion energy remains as bulk kinetic energy until the ejecta begins to decelerate at the Sedov radius. Thus, it has been widely believed that a negligible energy fraction of the SN ejecta energy can be used for high-energy emission in the first several days to months after the explosion. The hydrodynamical evolution of SNe is divided into several phases. Just after the core collapse, a SN shock propagates inside a stellar core or envelope, and the shock
is radiation mediated or even collisional (Weaver 1976). As the shock reaches the surface of the progenitor star, the photon diffusion time becomes short enough, and the shock breakout (at which the SN emission begins to escape) occurs (e.g., Matzner & McKee 1999). Then the SN shock starts to sweep up circumstellar material (CSM)\(^1\) and efficient CR acceleration begins to operate as in SNRs. However, for mass-loss rates that are typical of evolved massive stars, \(\sim 10^{-6} - 10^{-4} \, M_\odot \, \text{yr}^{-1}\), high-energy neutrino and gamma-ray emission is detectable only for nearby SN events (Murase 2018), because the SN ejecta are largely in the free expansion phase.

Interestingly, an increasing sample of SNe discovered by recent massive searches for optical and near-IR transients has revealed that strong shock interactions between the SN ejecta and a dense wind or CSM shell occur in various classes of explosive transients, as suggested by observations of Type Ibn, IIn, Ia-CSM, and Type II super-luminous supernovae (e.g., Smith et al. 2007; Miller et al. 2009; Ofek et al. 2013b,a; Margutti et al. 2014a; Ofek et al. 2014b,a; Margutti et al. 2017). This suggests that the pre-explosion eruption of the stellar material or inflation of its envelope might be ubiquitous (see Smith 2014, for a review). Although the origin of extended material is not well known, significant mass (\(\sim 10^{-3} - 10 \, M_\odot\)) may be ejected \(\sim 0.1 - 1 \, \text{yr}\) before the core-collapse event (e.g., Immler et al. 2008; Smith & McCray 2007; Smith 2013; Fransson et al. 2014; Mauerhan et al. 2014; Milisavljevic et al. 2015). For such objects, the energy dissipated by the shock is significantly enhanced (see a review Chevalier & Fransson 2016), and a substantial amount of CRs will be produced even in the early phase. The ambient density is so high that most CRs should be converted into neutrino and gamma-ray emission (i.e., the system is “calorimetric”). Such CR acceleration in dense environments has been seen by gamma-ray observations of novae (Ackermann et al. 2014). Murase et al. (2011) and Murase et al. (2014) suggested that non-thermal signatures (including neutrinos, gamma rays, X rays, submm and radio waves) can be used as a probe of the early stage of CR acceleration in SNe IIn. It is worth mentioning that interacting SNe and Type IIn SNe have also been suggested as Pevatrons, in particular accelerators of CRs beyond the knee energy at \(10^{15.5}\) eV (Svetsnikova 2003; Murase et al. 2014; Zirakashvili & Ptuskin 2016). They have also been discussed as one of the origins of IceCube’s neutrinos above 0.1 PeV (Zirakashvili & Ptuskin 2016; Petropoulou et al. 2017). Thus, searching for high-energy emission will give us clues to the CR origin as well as mechanisms of early-time particle acceleration and pre-explosion mass losses.

In this work, we present results of detailed calculations of non-thermal emission from interacting SNe. In the early stages of strongly interacting SNe such as Type IIn SNe, copious thermal photons are present, which inevitably initiate electromagnetic cascades via two-photon annihilation and subsequent synchrotron and inverse-Compton radiation. In addition, gamma rays and radio waves may be attenuated during their propagation in the CSM. The model is described in Section 2, and we apply our phenomenological time-dependent model to SN 2010jl (see Section 3). In particular, using the Pass 8 data of Fermi Large Area Telescope (LAT), we perform detailed analyses of gamma-ray emission from SN 2010jl and compare the limits with predictions of the theoretical model. To convey one of the main results in this work, we first show predicted neutrino and gamma-ray fluences together with the upper limit by Fermi LAT in Figure 1. The comparison between the theory and data implies that the energy fraction of CRs is constrained to be \(\epsilon_p < 0.05 - 0.1\). In Section 4, we provide a simplified time-integrated model, which can be useful when detailed data are not available. The model is then applied to SN Ibn 2014C, in addition to SN 2010jl. In Section 5, we additionally discuss the gamma-ray detectability of nearby SNe, and the results are summarized in Section 6. We use the notation

\[^1\] Strictly speaking, the external material can be a dense wind or CSM shell or even an inflated envelope.
\( Q = 10^5 Q_2 \) in CGS units unless noted otherwise.

2. HIGH-ENERGY EMISSION FROM INTERACTING supernovae

2.1. Overview

For a wide range of parameters of SNe indicating interactions with a dense CSM\(^2\), it has been shown that the SN shock becomes collisionless and non-radiation mediated when the Thomson optical depth \( \tau_T \) is less than \( \sim c/V_s \) (Murase et al. 2011; Katz et al. 2011). Note that the formation of collisionless shocks around the photon breakout radius \( R_{\text{bo}} \) would not occur for a steep density profile expected in the outer stellar envelope. The maximum velocity of the pre-shock CSM is limited by the radiation pressure, which implies that the collisionless shock may form at \( \gtrsim [2(3 - w)]^{1-w} R_{\text{bo}} \), where \( w \) is the ambient density slope. With an CSM (for which \( w \sim 0 - 2 \) is typically expected), the shock should become collisionless around \( R_{\text{bo}} \). Unless the CSM density is too large for Coulomb losses to be relevant (Murase et al. 2014), the CR acceleration will also begin after photons start to escape at the breakout time, \( t_{\text{bo}} \). Then, CRs interact with CSM nucleons via \( pp \) interactions, leading to neutrinos, gamma rays, and X rays, followed by longer timescale radio/submm emission from secondary electrons and positrons.

How much is the dissipation energy? In the frequently adopted simplified SN ejecta model, the dissipation energy is estimated to be \( M_{\text{cs}} \epsilon_{\text{ej}}/(M_{\text{ej}} + M_{\text{cs}}) \) (e.g., Murase et al. 2011; Petropoulou et al. 2016), where \( M_{\text{cs}} \) is the CSM mass and \( M_{\text{ej}} \) is the ejecta mass. However, the realistic SN ejecta has a density structure as a function of velocity, and there is a high-velocity tail. Murase (2018) considered a time-dependent model, using a self-similar solution (Chevalier 1982; Nadezhin 1985; Moriya et al. 2013). In this more detailed model, as a function of the ejecta velocity \( V \), the dissipated energy is given by \( \epsilon_{\text{ej}}(> V) \propto V^{5-\delta} \), where \( \delta \) is the index of the outer ejecta density profile. Here one should keep in mind that the higher-velocity ejecta is more efficiently dissipated, which significantly enhances the detectability of high-energy emission compared to the simple estimate (Murase 2018). While \( \delta = 10 \) (for a convective envelope) and \( \delta = 12 \) (for a radiative envelope) are often assumed (Matzner & McKee 1999), realistic values of \( \delta \) are uncertain for Type II SN SNe, because the ejecta may already experience some CSM interactions prior to the major dissipation (van Marle et al. 2010). Note that smaller values of \( \delta \) are also indicated for trans-relativistic SNe that are associated with low-luminosity GRBs that may be driven by jets (e.g., Margutti et al. 2014b).

We consider an SN shock that propagates in the CSM. For simplicity\(^3\), we assume an CSM density profile of

\[
\rho_{\text{cs}}(R) = DR^{-w} \equiv DR_0^{-w} \left( \frac{R}{R_0} \right)^{-w},
\]

where \( w = 2 \) corresponds to the wind density profile. The target nucleon density is given by

\[
n_N = \frac{D}{m_H} R^{-w} = \frac{D}{m_H R_0^w} \left( \frac{R}{R_0} \right)^{-w} \\
\approx 3.0 \times 10^{10} \text{ cm}^{-3} D_s R_{0.15}^{-2} R_{15}^{-w},
\]

where \( D_s = D/(5 \times 10^{16} \text{ g cm}^{-1}) \) (\( D = D \) for \( w = 2 \)) and \( R_0 \) is an arbitrary radius characterizing the CSM radius. Note that \( D_s = 1 \) corresponds to \( D = M_w/(4\pi V_w) \) with a wind mass-loss rate of \( M_w = 0.1 \text{ M}_\odot \text{ yr}^{-1} \) and a wind velocity of \( V_w = 100 \text{ km s}^{-1} \).

As noted, a faster component of the ejecta is decelerated earlier, and the kinetic luminosity that can be used for dissipation at the forward shock is,

\[
L_s = 2\pi \rho_{\text{cs}} R_s^2 V_s^3 \approx 3.9 \times 10^{43} \text{ erg s}^{-1} D_s R_{0.15}^{-2} \times R_{s,15}^{2-w} (V_s/5000 \text{ km s}^{-1})^3,
\]

where \( R_s \) is the shock radius, \( V_s \) is the forward shock velocity. The bolometric, thermal radiation luminosity (used for thermal SN emission in the optical and/or X-ray bands) is expressed as \( L_{\text{rad}} = \epsilon_{\text{rad}} L_s \), where \( \epsilon_{\text{rad}} \) is the energy fraction carried by the radiation.

The neutrino and gamma-ray emission is governed by the effective optical depth of inelastic \( pp \) interactions, \( f_{pp} \), which is estimated to be

\[
f_{pp} \approx \kappa_{pp} \sigma_{pp} c n_N (R_s/V_s) \\
\approx 27 D_s R_{0.15}^{-2} R_{s,15}^{1-w} (V_s/5000 \text{ km s}^{-1})^{-1},
\]

where \( \sigma_{pp} \approx 3 \times 10^{-26} \text{ cm}^2 \) is the inelastic \( pp \) cross section and \( \kappa_{pp} \approx 0.5 \) is the proton inelasticity, respectively. Here we have used \( f_{pp} \approx \kappa_{pp} \sigma_{pp} c (r_{sc} n_N) (\Delta_s/V_s) \approx \kappa_{pp} \sigma_{pp} c n_N (R_s/V_s) \), where \( r_{sc} \) is the shock compression ratio and \( \Delta_s \approx R_s/r_{sc} \) is the size of the shocked region. Because the CR energy density in the post-forward-shock region is estimated to be \( \epsilon_{p} \rho_{\text{cs}} V_s^2 /2 = \epsilon_p L_s/(4\pi R_s^2 V_s) \),

\(^2\) We stress that the physical situation is quite different in ordinary SNe such as Type II-P and II-L SNe, in which the CSM is not dense enough that we can naturally expect that the conventional DSA operates (Murase 2018). On the other hand, in Type II SNe, the shock is initially radiation-mediated, so the onset of CR acceleration is uncertain and worth investigating.

\(^3\) The CSM profile may not be a simple power law, and the shell-like structure has often been observed (e.g., Margutti et al. 2017). In general, we may not apply self-similar solutions to describe the shock dynamics.
for example, the gamma-ray luminosity is given by

\[ L_s \approx \frac{1}{3} \min \left[ \frac{M_{\text{cs}}(< R_s)}{m_p} \kappa_{pp} \sigma_{pp} \epsilon_p L_s c, \epsilon_p L_s \right] \]

\[ \approx \frac{1}{3} \min[f_{pp}, 1] \epsilon_p L_s , \quad (5) \]

where \( \epsilon_p \) is the energy fraction of accelerated CR protons and \( \sim 0.1 \) is typically expected in the DSA theory for quasi-parallel shocks (Caprioli & Spitkovsky 2014a). Such a value is also motivated by the hypothesis that interacting SNe are responsible for the observed CR flux around or beyond the knee energy at \( \sim 3 \) PeV (Sveshnikova 2003; Murase et al. 2014). Note that \( M_{\text{cs}}(< R_s) = \Delta \Omega D_{\Delta s} \) in the wind case.

The principal parameters are CSM nucleon density \( n_N \), shock radius \( R_s \), and shock velocity \( V_s \) (Murase et al. 2011; Margutti et al. 2014a). The differential gamma-ray luminosity is approximately:

\[ E_s L_E_s \approx \frac{1}{3} \min[f_{pp}, 1] E_p L_{E_p} \]

\[ \approx 1.3 \times 10^{41} \text{erg s}^{-1} \min[f_{pp}, 1] \]

\[ \times \left( \frac{E_p}{0.1 m_p c^2} \right)^{2-s_p} \epsilon_p c^{-1} R_{p0,1}^{-1} \]

\[ \times D_s R_{s,15}^{-2} R_{s,15}^{-w/2} (V_s/5000 \text{ km s}^{-1})^3 , \quad (6) \]

where \( s_p \) is the proton spectral index and \( R_{p0} \approx 5 - 10 \) is the normalization factor that is given by

\[ E_p L_{E_p} \equiv E_p \frac{dL_p}{d\nu} = \epsilon_p L_s \left( \frac{E_p}{m_p c^2} \right)^{2-s_p} . \quad (7) \]

We parameterize the magnetic field by \( U_B \equiv \epsilon_B (\theta_{B0} V_s^2/2) \) (where \( U_B \) is the magnetic energy density), which leads to

\[ B \equiv (\epsilon_B 4 \theta_{B0} V_s^2)^{1/2} \]

\[ \approx 40 \text{G} \epsilon_B^{1/2} D_s^{-1/2} R_{s,15}^{-2} R_{s,15}^{-w/2} (V_s/5000 \text{ km s}^{-1}) , \quad (8) \]

where \( \epsilon_B \sim 0.001 - 0.01 \) is assumed. Although such a value is motivated by observations of radio SNe (e.g., Chevalier et al. 2006; Maeda 2012) and the hypothesis that these SNe contribute to the observed CR flux beyond the knee energy, it is highly uncertain whether the maximum CR energy can exceed \( \sim 10 - 100 \) TeV. On the other hand, the significant amplification of magnetic fields may occur by various reasons. The CSM could be highly turbulent and magnetized, because the violent CSM eruptions may also be accompanied by shocks (Murase et al. 2014). The CSM may also be highly clumpy (Smith et al. 2009), in which the turbulent dynamo process could amplify both upstream and downstream fields (e.g., Xu & Lazarian 2017). The upstream magnetic field amplification with \( \epsilon_B \propto \epsilon_p M_A^{-1} \) (where \( M_A \) is the Alfvénic Mach number) could also be realized by CRs them-
ton fluxes at the same high energy is $\sim 10^{-3} - 10^{-2}$, implying that the energy fraction carried by DSA-accelerated CR electrons is $\epsilon_e \sim 10^{-4} - 10^{-3}$ for a flat energy spectrum (e.g., Katz & Waxman 2008). Electrons can be injected into the DSA once their Lorentz factor exceeds the shock transition layer, and we assume that the corresponding characteristic Lorentz factor is given by $\gamma_{t2} \sim (m_p/m_e)(V_s/c)$, above which the spectral index is $s_e = s_p$ (e.g., Park et al. 2015). For $\gamma_{t2} \gg 1$, the characteristic synchrotron frequency for the DSA is estimated to be

$$\nu_{t2} = \frac{3}{4\pi} \frac{\dot{\gamma}^2}{m_e c} \sim 160 \text{ GHz} \epsilon_{t2}^{1/2} D_s^{-1/2} R_{s,15}^{-w/2-1} \times R_{s,15}^{-w/2}(V_s/5000 \text{ km s}^{-1})^3. \quad (12)$$

Note that the conventional DSA may not be applied for electrons with lower Lorentz factors. It has been suggested that observations of SNe IIb and SNe IIn will enable us to probe electron acceleration in the shock transition layer (Maeda 2012, 2013; Murase et al. 2014). For a low-energy component of non-thermal electrons, the injection Lorentz factor is given by $\gamma_{t1} = [1 + (p_{t1}/m_ec^2)]^{1/2}$. If $p_{t1} \gg m_ec$, we have the conventional formula, $\gamma_{t1} = (\dot{\gamma} \epsilon_em_p)/(2f_e m_e)(V_s/c)^2$, where $\dot{\gamma}$ is the energy fraction of electrons with $\gamma_e \geq \gamma_{t1}$, $f_e$ is the number fraction, and $g_e = (p_e - 2)/(q_e - 1)$ for a low-energy spectral index, $q_e > 2$. We typically expect $p_{t1} \ll m_ec$, where one may approximate a low-energy electron spectrum as $\text{d}n_{e or} / \text{d}\gamma_e \propto \gamma_e^{-s}$ with $\gamma_{t1} = 1$. The steady-state index of electrons can be $\sim 3$ due to radiative energy losses, in which $\gamma_e \sim s_e$ is possible (Chevalier et al. 2006). Or, perhaps, $q_e > s_e$ (allowing $\dot{\gamma} \sim 0.01$) could be realized by other processes such as the shock-drift acceleration mechanism at quasi-perpendicular shocks (e.g., Matsumoto et al. 2017).

The high-frequency synchrotron luminosity (at $\nu > \nu_{t2}$) in the fast cooling case is

$$\nu L_{\nu}^{t2} \approx \frac{1}{2(1 + Y)} E_e L_{E_e} \approx 2.0 \times 10^{38} \text{ erg s}^{-1} (1 + Y)^{-1} \left(\frac{\nu}{\nu_{t2}}\right)^{2-s_p} \epsilon_{e,-4} R_{t0,1}^{-1} \times D_s R_{0,15}^{-2} R_{s,15}^{-w}(V_s/5000 \text{ km s}^{-1})^3 f_{esc}, \quad (13)$$

where $\epsilon_e(< \dot{\gamma})$ is the energy fraction of DSA-accelerated electrons. Thus, the lepton origin of radio emission predicts:

$$\frac{E_{\nu} F_{\nu}}{\nu^2} \approx \frac{2\epsilon_p R_{t0}}{3\epsilon_e R_{t0}^{1/2}} \frac{(E_{\gamma} / 0.1 m_p c^2)^{2-s_p}(\nu/\nu_{t2})^{2-s_p}}{\nu / 100 \text{ GHz}} \min[f_{pp}, 1]$$

$$\approx 400 \left(\frac{E_{\gamma}}{1 \text{ GeV}}\right)^{2-s_p} \left(\nu / 100 \text{ GHz}\right)^{2-s_p} (10^{-3} \epsilon_p/\epsilon_e)$$

$$\times \left(\frac{R_{t0}/R_{t0}}{\epsilon_{e,-4}}\right)^{3/2} \left(\frac{Y}{\nu_{t2}}\right)^{2-\beta} \times (V_s/5000 \text{ km s}^{-1})^{-2} \min[f_{pp}, 1] f_{esc}^{-1}. \quad (14)$$

where $Y < 1$ is assumed. The ratio depends on $R_s$ and $V_s$ differently from that in the hadronic scenario, so the time-dependence of the gamma-ray to radio fluxes is relevant to discriminate between the hadronic and leptonic models. So far, we have ignored various processes that can suppress the radio emission. More generally, low-frequency emission is affected by various effects such as synchrotron self-absorption, free-free absorption, and Coulomb cooling, which will be included in our numerical calculations.

In Type IIn SNe, $\epsilon_p \gg \epsilon_e$ allows us to expect that both gamma-ray emission and high-frequency radio emission are dominated by the hadronic component. In the high-frequency limit (i.e., $\nu > \nu_h, \nu_{t2}$), in which either hadronic or leptonic model predicts the same spectrum, $\nu F_{\nu} \propto \nu^{2-\beta}$, the condition for the secondary emission to overwhelm the primary component is written:

$$\min[1, f_{pp}] \frac{\epsilon_{p-1}}{\epsilon_{e,-4}} \left(\frac{Y}{\nu_{t2}}\right)^{2-\beta} \gtrsim 6 \times 10^{-3}, \quad (15)$$

where $R_{t0} = R_{t0}$ and $s_p = s_e$ are assumed, and $\beta = 1 + s/2$ is the high-energy synchrotron photon index $\epsilon_e$.

2.2. Phenomenological Model

In cases of well-observed Type IIn SNe such as SN 2010jl, parameters on SN dynamics can be determined by the observational data of (mostly) thermal emission from the SNe. We here focus on the forward shock emission (see Chevalier & Fransson 2016; Murase et al. 2011, for a discussion on the reverse shock emissions), and consider a single radiation zone with the size $\Delta R_s \approx R_s$. In a time-dependent model, we need to know three quantities, $\alpha_{cs}, R_s$, and $V_s$ as a function of time $t$. If all three quantities are described by power laws, which are assumed throughout this work for simplicity, one needs five parameters, $D, w, R_0, t_0$, and the temporal index $a$ to describe the SN dynamics. Here, just for convenience, we take $R_0 = R_{bo}$ and $t_0 = t_{bo}$, where $R_{bo}$ is the photon breakout radius and $t_{bo}$ is the breakout time. Our formalism enables us to predict non-thermal fluxes from

4 We note that Murase et al. (2014) used $\epsilon_e = 10^{-4}$ in Eqs. (58) and (59) and $q$ should be the photon index there.
the observational data only with a few free parameters such as \( \epsilon_p \) and \( s_p \).

The CSM density given by Equation (1) can be rewritten:

\[
\rho_{\text{CS}}(R) = D R_{\text{bo}}^2 \left( \frac{R}{R_{\text{bo}}} \right)^{-w},
\]

where \( R_0 = R_{\text{bo}} \) is used. The CSM nucleon density is given by \( n_N = \rho_{\text{CS}}/m_H \).

Assuming a power-law evolution, the shock radius and velocity are parameterized as

\[
R_s = R_{\text{bo}} \left( \frac{t}{t_{\text{bo}}} \right)^{\alpha},
\]

and

\[
V_s = V_{\text{bo}} \left( \frac{t}{t_{\text{bo}}} \right)^{-1/a},
\]

where \( V_{\text{bo}} = aR_{\text{bo}}/t_{\text{bo}} \). Note that \( R_s \) and \( V_s \) are determined by the observational data. If the self-similar solution for a spherical CSM is adopted, the index \( \alpha \) is explicitly given by \( \alpha = (\delta - 3)/(\delta - w) \), where \( \delta \approx 7 - 12 \) is the index of the outer ejecta profile, \( \rho_{\text{ej}} \propto t^{-3}(r/t)^{-3} \) (e.g., Matzner & McKee 1999).

The shock power is calculated as

\[
L_s = \frac{(\Delta \Omega/2)}{D V_s^3} \left( \frac{t}{t_{\text{bo}}} \right)^{5\alpha-3-aw} \propto t^{-\alpha},
\]

where \( \alpha = 3 - a(5 - w) \). If we assume the self-similar solution, which is valid until the deceleration of the inner ejecta starts, we obtain \( \alpha = [\delta - 3)(w - 2) + 3(3 - w)]/[\delta - w] \) (e.g., Moriya et al. 2013; Ofek et al. 2014b; Chevalier & Fransson 2016; Murase 2018). Note that \( \Delta \Omega = 4\pi \) in the spherical geometry of the CSM, and it has been argued that the CSM could be aspherical or even clumpy (e.g., Smith et al. 2009; Margutti et al. 2014a; Smith 2014; Katsuda et al. 2016). Only a fraction \( \epsilon_{\text{rad}} < 1 \) of the shock power is used for the radiation luminosity, \( L_{\text{rad}} = \epsilon_{\text{rad}} L_s \).

We assume that the DSA works as in SNRs, and consider a power-law form,

\[
\frac{dn_{\text{CR}}}{dp} \propto p^{-s_p} e^{-p/p_{\text{max}}},
\]

The maximum momentum, \( p_{\text{max}} \), is determined by CR escape and cooling processes such as \( pp \) interactions, Bethe-Heitler pair production, and adiabatic losses.\(^5\)

We also introduce an escape boundary of 0.6\( R_s \) to estimate the maximum energy. The DSA theory for a quasi-parallel shock predicts \( s_p = 2.0 \), whereas a steeper spectrum of \( s_p \approx 2.2 - 2.4 \) is inferred by GeV-TeV gamma-ray observations of the young SNR Cas A (e.g., Ahnen et al. 2017, and references therein).

The normalization of the CR spectrum is given by

\[
U_p = \int_{p_{\text{max}}}^{p_{\text{max}}} dp \ E_p \frac{dn_{\text{CR}}}{dp},
\]

where \( U_p \approx \epsilon_p L_{\gamma}/(\Delta \Omega R_s^2 V_s) \) is used. Throughout this work, we choose \( \epsilon_p = 0.05 \) as a fiducial parameter, based on the observation of Cas A (Ahnen et al. 2017). We only consider fresh CRs because the CRs lose their energies via adiabatic losses during the dynamical time (as well as via other energy-loss processes). A more quantitative treatment is possible by solving kinetic equations of protons, which is important only if the luminosity declines more rapidly than \( L_s \propto t^{-1} \). Our assumption to consider the fresh CRs is justified for \( w < 3 \), and indeed seen in intensively studied SNe IIn (Moriya et al. 2013). Such an approximation is often used in the context of GRBs (Mészáros 2006; Murase 2008). Importantly, when the hadronic cooling of CR protons is dominant and its effective time scale, \( t_{pp} \approx (\kappa_{pp}\sigma_{pp}n_N)^{-1} \), is shorter than the dynamical time, \( t_{\text{dyn}} \approx R_s/V_s \), the luminosity of secondary particles such as neutrinos and gamma rays is limited by \( L_p \) (see Equation 5). The system is “calorimetric” and energy conservation should not be violated.

For a given set of parameters describing hydrodynamics evolution of the parameters, we calculate energy densities of neutrinos, gamma rays, and electrons/positrons, by exploiting the following formulas:

\[
\frac{dn_{\text{CR}}}{dp} \propto p^{-s_p} e^{-p/p_{\text{max}}},
\]

\[\text{where } \xi_{\nu}, \xi_{\gamma}, \text{ and } \xi_e \text{ represent multiplicities of the secondaries.}
\]

We use the differential cross sections of \( pp \) interactions given by Kachel et al. (2006), and the total \( pp \) cross section is adjusted to the post-LHC formula by Kafexhiu et al. (2014). Here the volume of the radiation zone is approximated as \( V \approx \Delta \Omega R_s^3/3 \).

In the previous work, Murase et al. (2011), the secondary emissions were calculated ignoring effects of electromagnetic cascades. In this work, using the code that was previously developed in Murase (2018), we solve the

\[\text{At sufficiently high energies, the wave damping due to neutral-ion collisions in the upstream region can be relevant as in partially-ionized shocks of SNRs (Murase et al. 2011), but GeV-TeV gamma-ray and neutrino emission would not be much affected.}\]
following kinetic equations:
\[
\begin{align*}
\frac{\partial n_{E_{r}}^{(\gamma)}}{\partial t} & = \frac{\partial n_{E_{r}}}{\partial t} - \frac{\partial}{\partial E_{r}} [(P_{IC} + P_{syn} + P_{ff} + P_{ad} + P_{Con}) n_{E_{r}}] \\
+ \dot{n}_{E_{r}}^{\text{inj}} & \\
\frac{\partial n_{E_{r}}^{(\gamma)}}{\partial t} & = - \frac{n_{E_{r}}^{\gamma}}{t_{\gamma}} - \frac{n_{E_{r}}^{\gamma}}{t_{\text{mat}}} + \frac{n_{E_{r}}^{\gamma}}{t_{\gamma}} + \frac{\partial n_{E_{r}}^{(IC)}}{\partial t} + \frac{\partial n_{E_{r}}^{(syn)}}{\partial t} \\
+ \frac{\partial n_{E_{r}}^{(ff)}}{\partial t} + \dot{n}_{E_{r}}^{\text{inj}},
\end{align*}
\]
(23)
where
\[
\begin{align*}
t_{\gamma}^{-1} & = \int dE_{\gamma} n_{E_{r}}^{\gamma} \int \frac{d \cos \theta}{2} \hat{c} \sigma_{\gamma\gamma}, \\
\frac{\partial n_{E_{r}}^{(IC)}}{\partial t} & = \int dE_{e} n_{E_{r}}^{e} \int dE_{r} n_{E_{r}}^{\gamma} \int \frac{d \cos \theta}{2} \hat{c} \frac{d \sigma_{IC}}{dE_{\gamma}}, \\
\frac{\partial n_{E_{r}}^{(syn)}}{\partial t} & = \int dE_{e} n_{E_{r}}^{e} \int dE_{r} n_{E_{r}}^{\gamma} \int \frac{d \cos \theta}{2} \hat{c} \frac{d \sigma_{syn}}{dE_{\gamma}}, \\
\text{and } \frac{\partial n_{E_{r}}^{(ff)}}{\partial t} & \text{ represents bremsstrahlung emission from non-thermal electrons and positrons (Jackson 1975). Here } \hat{c} = (1 - \cos \theta)c \text{ (where } \theta \text{ is the angle between two particles), } t_{\gamma} \gamma \text{ is the two-photon annihilation time, } t_{\text{mat}} \text{ is the energy-loss time due to Compton scattering and Bethe-Heitler pair-production (Chodorowski et al. 1992) processes, } t_{\text{esc}} \approx R_{s}/c \text{ is the photon escape time, } P_{IC} \text{ is the inverse-Compton energy-loss rate (where the Klein-Nishina effect is fully taken into account), } P_{syn} \text{ is the synchrotron energy-loss rate (Rybicki & Lightman 1979), } P_{ff} \text{ is the non-thermal bremsstrahlung energy-loss rate (Schlickeiser 2002), } P_{ad} \text{ is the adiabatic energy-loss rate, and } P_{Con} \text{ is the Coulomb energy-loss rate (Schlickeiser 2002). The calculation during } t_{\text{syn}} \approx R_{s}/V_{s} \text{ essentially leads to quasi-steady photon spectra at } t. \\
\]
Bethe-Heitler process depends on the nucleus charge. Throughout this work, we assume a mass composition of \( x_\text{H} = 0.7 \), \( x_{\text{He}} = 0.25 \), and \( x_{\text{C/O}} = 0.05 \), leading to the effective charge, \( Z_{\text{eff}} \equiv \Sigma_i (2Z_i^2 / A_i) x_i = 2.25 \), and the inverse of the mean molecular weight per electron, \( \mu_e^{-1} = 0.85 \). At lower energies, the photoionization and excitation become relevant, for which we adopt the simple approximate opacity, \( K_{\text{pe}} \simeq 2.4 \times 10^{-2} \text{cm}^2 \text{g}^{-1} (\hbar \nu / 10 \text{keV})^{-3} \) (Morrison & McCammon 1983). For Type IIn SNe, non-thermal X-ray emission is usually masked by the thermal bremsstrahlung component, and our work has a more focus on gamma rays and radio waves.

On the other hand, radio emission is affected by the synchrotron self-absorption, free-free absorption by free electrons, and the so-called Razin-Tsytovich effect. We implement \( 1 - \exp(-\tau_{\text{sa}}) / \tau_{\text{sa}} \) for the self-absorption in the radiation zone, where \( \tau_{\text{sa}} \) is calculated for the energy distribution of electrons and positrons, obtained by our numerical calculations (Rybicki & Lightman 1979). The free-free absorption optical depth, \( \tau_{\text{ff}} \), is:

\[
\tau_{\text{ff}}(\nu) \approx \int_{R_s} dR \frac{8.5 \times 10^{-28} (\frac{\nu}{10^{10} \text{Hz}})^{-2.1}}{n_e^{2}}
+ \left( \frac{T_{\text{cs}}}{10^4 \text{K}} \right)^{-1.35} \left( \frac{1 - e^{-\nu / kT_{\text{cs}}}}{\hbar \nu / kT_{\text{cs}}} \right),
\]

ignoring the detailed dependence on the metallicity. We expect that the immediate upstream region is ionized by X rays, and we use \( f_{\text{sup}}^{\text{mat}} = \exp(-\tau_{\text{ff}}^{\nu}) \). Note that \( T_{\text{cs}}^{u} \) is a pre-shock CSM temperature. Because the far upstream region is expected to be partially ionized or nearly neutral, the above estimate gives conservative results. We also include the Razin-Tsytovich effect simply by \( f_{\text{sup}}^{\text{mat}} = \exp(-\nu_{\text{RT}} / \nu) \), where \( \nu_{\text{RT}} \) is the Razin-Tsytovich frequency. See discussions in Murase et al. (2014) for details of these physical effects.

The differential luminosity of non-thermal radiation is calculated by

\[
E_{\gamma} L_{\gamma} = \frac{(E_{\gamma}^2 n_{E_{\gamma}}) \nu f_{\text{sup}}^{\text{mat}}}{\nu_{\text{esc}}},
\]

For a clumpy or aspherical CSM, the attenuation due to matter (not radiation) can be significantly alleviated, which is especially important for the detectability of radio emission. In such a case, one could replace the suppression factor due to interactions with matter (\( f_{\text{sup}}^{\text{mat}} \)) with \( \max(f_{\text{sup}}^{\text{mat}}, f_{\text{esc}}^{\text{mat}}) \), where \( f_{\text{esc}}^{\text{mat}} \) is the photon escape fraction that depends on details of the CSM geometry. Note that \( f_{\text{sup}}^{\text{mat}} = 1 \) for neutrinos, and the flavor mixing is taken into account.

3. APPLICATION TO SN 2010JL

3.1. Theoretical Prediction

![Figure 2](image-url)  
**Figure 2.** Theoretical predictions for hadronic gamma-ray spectra from SN 2010JL at different times, obtained by our time-dependent numerical model. We show cases after (thick curves) and before (thin curves) gamma-ray attenuation in the CSM. Note that electromagnetic cascades in the radiation zone are taken into account. The CR parameters are \( \epsilon_p = 0.05 \) and \( s_p = 2.2 \).

![Figure 3](image-url)  
**Figure 3.** Modeled hadronic gamma-ray light curves of SN 2010JL, corresponding to Figures 1 and 2. Possible gamma-ray attenuation in the GeV range, indicated by the thick curves, is dominated by the Bethe-Heitler pair-production process in the pre-shock CSM. Note that this attenuation is irrelevant for late-time emission that dominates the gamma-ray fluence.

We apply our calculation method to SN 2010JL, adopting the physical parameters estimated by Ofek et al. (2014b) (see Table 1). SN 2010JL was found in the star-forming galaxy UGC 5189A whose redshift is \( z = 0.0107 \) corresponding to a distance of \( d = 49 \text{Mpc} \) (Ofek et al. 2014b). The SN coordinates are R.A. = \( 09^h42^m53.3^s \) and Dec. = \(+09^\circ29'42''\).

Although our results on gamma rays are unaffected by interactions with X rays, we also include thermal X rays as an additional photon field. For simplicity, the X-ray energy density at the source is implemented by using the formula of bremsstrahlung emission with an immediate
Table 1. Source parameters of SN 2010jl, used in our time-dependent model. See text for details (see also Ofek et al. 2014b). The derived shock power corresponds to $\epsilon_{sn} = 0.25$.

| $D_s$ | $w$ | $t_{iso}$ [d] | $R_{iso}$ [cm] | $a$ | $L_{iso}$ [erg/s] | $T_{iso}$ [K] | $\epsilon_B$ | $\epsilon_p$ |
|------|----|-------------|-------------|----|-----------------|-------------|----------|----------|
| 6    | 2  | 20          | $1.1 \times 10^{15}$ | 0.875 | $5.5 \times 10^{43}$ | 9000        | $1.5 \times 10^{-2}$ | 0.05     |

Figure 4. Radio light curves corresponding to Figure 3. The attenuation of radio waves during the CSM propagation is too strong. We here show cases for radio emission from the radiation zone (thin curves) and escaping emission for $f_{esc} = 0.03$ (thick curves).

downstream temperature of $(3/16)\mu m_H V_s^2$, where $\mu$ is the mean molecular weight. (Note that the post-shock temperature can be much lower in the far downstream for a radiation-dominated or radiative shock.)

The results on modeled gamma-ray spectra and light curves are shown in Figures 2 and 3. We consider hadronic gamma-ray production, and one sees that pionic gamma rays give a dominant contribution. Gamma-ray attenuation by the Bethe-Heitler pair-production process in the CSM is important at early times around the photon breakout time, but at late times the gamma-ray flux is only moderately suppressed below $\sim 20 - 30$ GeV. Note that this effect is less important if the shock velocity is higher (Murase et al. 2014), and its overall influence on the fluence (to $t \sim 300$ d) is only a factor of 2 at most (see Figure 1). This means that GeV gamma rays can be used as a much more direct probe of shock interactions in dense environments such that $\tau_T > 1$, than visible light, X rays, and radio waves that are subject to scatterings and attenuation.

In addition, the two-photon annihilation ($\gamma\gamma \rightarrow e^+e^-$) due to interactions with SN photons is crucial above a cutoff energy at $\sim 20 - 30$ GeV, which is consistent with $E_\gamma (3kT_{sn}) \approx m_e^2 c^4$. Note that we have assumed a constant SN temperature of $T_{sn} = 9000$ K assuming the gray body radiation. Electrons and positrons from muon decay as well as those from $\gamma\gamma \rightarrow e^+e^-$ radiatively cool mainly via synchrotron radiation, but a fraction of their energy is used for inverse-Compton emission, which can be seen below $\sim 0.1$ GeV energies. The light curves are shown in Figure 3, where one sees that the gamma-ray attenuation in the CSM can be important until $\sim 100$ d, which makes the predictions for gamma-ray light curves different from those without the attenuation effects.

We consider light curves from $t = 20$ d to $t = 316$ d. The time window of our theoretical calculation and Fermi-LAT gamma-ray search is motivated by the sharp decline of the observed optical light curve at $t \sim 300$ d. Its origin has been under debate (e.g., Ofek et al. 2014b; Maeda et al. 2013), and there may be a break in the bolometric light curve itself (Fransson et al. 2014). The gamma-ray and neutrino luminosities are proportional to min[1, $f_{pp}e_pL_s$]. With $f_{pp} \gtrsim 1$, they will trace the bolometric luminosity that could abruptly drop after the shock reaches the edge of the CSM (whose radius is characterized by $R_s$).

We also calculate radio light curves in Figure 4. However, as expected, radio emission is strongly suppressed due to strong absorption in the CSM as well as synchrotron self-absorption in the radiation zone. In particular, the free-free absorption process is crucial especially when the pre-shock CSM is uniform and spherical, and we do not expect radio detection even if we assume a rather high temperature of $T_{cs} = 3 \times 10^5$ K. However, a fraction of the radio emission could escape if the CSM is aspherical or even clumpy, which has been suggested observationally for some Type IIn SNe (Smith 2014; Margutti et al. 2014a). Also, a fraction of escaping radio waves could be enhanced if the pre-shock CSM is mostly neutral. To discuss this effect, we here assume that 3% of the emission can escape because of the possible incomplete CSM coverage, while the attenuation due to radiation fields is fully taken into account. The radio emission from SN 2010jl had not been detected for about a year, which is consistent with the strong absorption. The radio observations of SN 2010jl were carried out with the Karl G. Jansky Very Large Array, and detections were reported $\sim 600 - 700$ d after the explosion (Chandra et al. 2015). Although the detailed modeling of the radio emission is beyond the scope of this work, the radio data show a late time flux with $\sim 0.1$ mJy, which is roughly consistent with our predictions of the hadronic scenario if $\sim 3\%$ of the emission can avoid interactions with electrons in the matter.

3.2. Fermi-LAT Data Analysis and Implications

Dedicated searches for gamma-ray emission from interaction SNe were first performed by Ackermann et al.
The SN sample used in the past stacking analysis include SN 2010jl. In this work, focusing on SN 2010jl, we re-analyze the Fermi-LAT data with the Pass 8 SOURCE class\(^7\). There are two significant improvements compared to the previous work. First, observationally, the Pass 8 data benefit from improved reconstruction and event selection algorithms with respect to the previous data release Pass 7 leading to a significantly improved angular resolution and sensitivity (Atwood et al. 2009) and therefore provide improved gamma-ray constraints. Second, the rich observational data on SN 2010jl allows us to derive detailed physical constraints on the possibility of CR ion acceleration in interacting SNe. In Ackermann et al. (2015), simple gamma-ray spectra with neither attenuation nor cascades were used, whereas we employ more realistic gamma-ray spectra by including these detailed effects. Also, thanks to the time-dependent multi-wavelength data for the SN, we are able to convert the gamma-ray limits into the bounds on the CR energy fraction, which is the quantity of particular interest.

We perform a binned analysis (i.e., binned in space and energy) using the standard Fermi-LAT Science-Tools package version v10r01p01 available from the Fermi Science Support Center\(^8\) (FSSC) and the PSR2\_SOURCE\_V6 instrument response functions. Otherwise the analysis is identical to the one described in Ackermann et al. (2015). The results of our updated gamma-ray data analysis at different integration times are shown in Figure 5. We here plot the logarithm of the likelihood ratio, \(-\Delta \ln L \equiv \ln(L/L_0)\), as a function of energy. Here \(L_0\) is the likelihood evaluated at the best-fit parameters under a background-only hypothesis, whereas \(L\) is the likelihood evaluated at the best-fit model parameters with a candidate point source at the SN position. See Ackermann et al. (2015) for details on the likelihood analysis.

Both differential and spectrum-integrated upper limits on gamma-ray fluxes averaged over a given time window are shown. At lower energies, the flux sensitivity approximately scales as \(\propto t^{-1/2}\), as expected in the background-dominated regime. At high energies, it scales as \(\propto t^{-1}\) at early times and then becomes \(\propto t^{-1/2}\). Note that the spectrum-integrated flux limits that depend on theoretical flux templates are typically several times stronger than the differential flux limits, for a hard

---

\(^7\) [http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Pass8_usage.html](http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Pass8_usage.html)

\(^8\) [http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Pass8_usage.html](http://fermi.gsfc.nasa.gov/ssc/data/analysis/documentation/Pass8_usage.html)
spectrum with \( s \sim 2 \).

Based on these results, we place quantitative limits on the energy fraction of CR protons, \( \epsilon_p \). This is done by convolving the gamma-ray spectra obtained by the theoretical calculations (Section 3) and the differential upper limits shown in Figures 5 and 6. For different integration times from 20 d to 50.24 d, 100.24 d, and 251.79 d, the derived 95% CL limits for \( s_p = 2.2 \) are \( \epsilon_p \leq 0.75 \) (\( \epsilon_{sn}/0.25 \)), \( \epsilon_p \leq 0.21 \) (\( \epsilon_{sn}/0.25 \)), and \( \epsilon_p \leq 0.066 \) (\( \epsilon_{sn}/0.25 \)), respectively. See Figure 1 for the comparison between our theoretical predictions and the gamma-ray limit from the Fermi-LAT data. In Figure 1, the possible effect of gamma-ray attenuation in the pre-shock CSM is also indicated, and the constraints on \( \epsilon_p \) can be somewhat improved if the gamma-ray attenuation in the CSM is completely negligible. Note that \( \epsilon_p = 0.05 \), which is indicated by the observation of the Galactic SNR Cas A, is still consistent with the non-detection of gamma rays from this SN IIn, and the upper limit can be somewhat weaker for larger values of \( \epsilon_{sn} \) (as we are constraining \( \epsilon_p L_s = (\epsilon_p/\epsilon_{sn}) L_{sn} \) via Equation 19). Nevertheless, our result, say \( \epsilon_p \lesssim 0.1 \) more conservatively, clearly suggests that we have reached the interesting parameter space for the purpose of probing the CR ion acceleration in embryonic SNRs embedded in a high-density material.

The constraints on \( \epsilon_p \) are quite insensitive to \( s_p \), because the predicted GeV gamma-ray spectra are similar for different values of \( s_p \). Based on the results shown in Figure 6 from left to right, we obtain \( \epsilon_p \leq 0.047 \) (\( \epsilon_{sn}/0.25 \)) (for \( s_p = 2.0 \)), \( \epsilon_p \leq 0.052 \) (\( \epsilon_{sn}/0.25 \)) (for \( s_p = 2.2 \)), and \( \epsilon_p \leq 0.073 \) (\( \epsilon_{sn}/0.25 \)) (for \( s_p = 2.4 \)), respectively. In any case, given that there are uncertainties in the source parameters used in our theoretical model, we conclude that the CR ion energy fraction in SN 2010jl is constrained to be less than \( \sim 10\% \). Note that Figure 1 corresponds to the case for \( s_p = 2.2 \).

4. SIMPLIFIED MODEL

In the previous sections, we described the time-dependent model to calculate non-thermal emissions from interacting SNe, and considered SN 2010jl as one of the applications. As shown in Murase (2018), such a time-dependent model is essential, because the detectability of high-energy neutrinos and gamma rays depends on the signal-to-background ratio for such long-duration transients. However, detailed SN data in the optical band and/or at other wavelengths may not always be available. Then, a simpler model can still be useful in such cases where the quality of the observational data is rather limited. In the following, we consider a simplified version of the model, for a given set of the principal parameters (\( n_X \), \( R_s \), and \( V_s \)) that represent typical values during the time interval of interest and may be obtained observationally for a specific characteristic period. The setup is similar to that in Murase et al. (2011), but we present more detailed calculations on electromagnetic cascades as well as attenuation during the photon propagation in the pre-shock CSM.

First, we apply the simplified model to SN 2010jl. The model parameters are listed in Table 2, which are based on the observations at \( t \sim 300 \) d (Ofek et al. 2014b; Fransson et al. 2014). The neutrino and gamma-ray spectra are shown in Figure 7. The results agree with those of the time-dependent model (compare Figure 7 to Figure 1). This implies that the simplified model is valid enough for the purpose of understanding physical properties of the emission. Also, we find that the pre-
Table 2. Source parameters of SN 2010jl, which are used in the simplified model. The CSM size is assumed to be \( \Delta R_s \approx R_s \). The derived shock power corresponds to \( \epsilon_{sn} \approx 0.25 \).

| Name  | \( n_N \) [cm] | \( R_s \) [cm] | \( V_s \) [cm s\(^{-1}\)] | \( L_{sn} \) [erg/s] | \( T_{sn} \) [K] | \( \epsilon_B \) | \( \epsilon_p \) | \( \epsilon_e \) |
|-------|----------------|----------------|----------------|---------------------|----------------|----------------|----------------|----------------|
| SN 2010jl | \( 1.8 \times 10^9 \) | \( 1 \times 10^{10} \) | \( 4 \times 10^8 \) | \( 2.7 \times 10^{33} \) | 9000 | \( 1.5 \times 10^{-2} \) | 0.05 | \( 5 \times 10^{-4} \) |

Table 3. Source parameters of SN 2014C, which are used in the simplified model. Motivated by observations (Margutti et al. 2017), we assume an CSM shell with \( \Delta R_s = 1.0 \times 10^{16} \) cm.

| Name  | \( n_N \) [cm] | \( R_s \) [cm] | \( V_s \) [cm s\(^{-1}\)] | \( L_{sn} \) [erg/s] | \( T_{sn} \) [K] | \( \epsilon_B \) | \( \epsilon_p \) | \( \epsilon_e \) |
|-------|----------------|----------------|----------------|---------------------|----------------|----------------|----------------|----------------|
| SN 2014C | \( 3.5 \times 10^6 \) | \( 6.4 \times 10^{16} \) | \( 4 \times 10^8 \) | \( 7 \times 10^{40} \) | 600 | \( 1.5 \times 10^{-2} \) | 0.05 | \( 2 \times 10^{-4} \) |

Figure 9. Broadband non-thermal spectra from SN Ibn 2014C at \( t = 396 \) d. The simplified model is used. The CR parameters are \( \epsilon_p = 0.05 \) and \( s_p = 2.2 \).

Predictions for gamma rays in the GeV range are not very sensitive to the assumption on \( s_p \). In Figure 8, we also show broadband non-thermal spectra expected in either hadronic or leptonic scenario. Pionic gamma rays produced via \( \pi^0 \rightarrow \gamma\gamma \) are denoted by “generated \( \gamma \). The spectra from the radiation zone are also depicted by the upper curves of the shaded regions, where the attenuation in the pre-shock CSM (i.e., the shock upstream) is not include yet. We find that low-frequency radio emission is modified compared to simple predictions of synchrotron emission from relativistic electrons with a simple power-law injection spectrum. This is because the Coulomb cooling of electrons and positrons becomes relevant in high-density environments, making the spectrum harder by distorting the lepton distribution and suppressing the resulting synchrotron emission. In addition, we expect non-thermal X-ray emission because relativistic electrons and positrons up-scatter SN photons to an energy of \( \sim \gamma_h^2 3kT_{sn} \approx 12 \text{ keV} \) \( T_{sn,4} \), where \( \gamma_h \approx 68 \). In reality, we expect strong photoelectric absorption and subsequent thermalization in the pre-shock CSM, so soft X rays are significantly suppressed in the SN 2010jl-like cases. Also, the non-thermal X-ray component can readily be overwhelmed by the thermal bremsstrahlung component. We also consider the leptonic scenario, in which the emission would be weaker for \( \epsilon_e/\epsilon_p \sim 10^{-3} - 10^{-2} \). The radio emission is significantly suppressed by the synchrotron self-absorption as well as the free-free absorption in the pre-shock CSM.

Second, we apply our code to SN 2014C that occurred at \( d = 15.1 \) Mpc. This SN was initially classified as an SN Ib, but in a year it started showing strong interactions with a dense CSM with \( M_{cs} \sim (1.0 - 1.5)M_{\odot} \). The model parameters listed in Table 3 are taken from the observational data at \( t \sim 400 \) d (Milisavljevic et al. 2015; Margutti et al. 2017). In this case, the observations indicated that the CSM has a shell-like structure, so we consider \( \Delta R_s < R_s \) and the CSM mass should be written as \( M_{cs} \sim \Delta R_s \Delta \Omega R_s^2 M_{\odot} / 4 \pi N_{cs} \). X-ray emission, which is consistent with bremsstrahlung emission, was observed by Chandra and NuSTAR (Margutti et al. 2017). We here implement the X-ray luminosity, \( L_X = 5 \times 10^{40} \text{ erg s}^{-1} \), and the X-ray temperature, \( kT_X = 18 \text{ keV} \), inferred from these observations. In any case, the results on photon spectra are not affected by target photons in the X-ray range. Thermal emission in the optical band declined at such late times, and the long-lasting dust emission was observed in the infrared band. For simplicity, we use \( L_{sn} = 7 \times 10^{40} \text{ erg s}^{-1} \) and \( T_{sn} = 600 \text{ K} \) following Tinyanont et al. (2016). The resulting spectra are shown in Figure 9. In this case, the gamma-ray emission would be too dim to detect because the CSM density is not high enough for the CR calorimetry to hold. The pionic gamma-ray component can be attenuated by the infrared photons only modestly in the 10 TeV range. Because of an electromagnetic cascade and the inverse-Compton scattering of the dust photons, the hadronic photon spectrum is flatter than the leptonic one. See also Model B in Murase et al. (2011). The radio signal in the 1-10 GHz range was detected (Margutti et al. 2017), which seems best explained by synchrotron emission from primary electrons. Although we show the case of \( T_{cs} = 3 \times 10^5 \text{ K} \), for demonstration, the free-free absorption can be more significant for a lower temperature of \( T_{cs} \sim 10^4 - 10^5 \text{ K} \). More
Detailed modeling that takes into account the CSM geometry would be necessary to robustly constrain $\epsilon_p$ and $\epsilon_\nu$. In any case, the hadronic scenario (with an CR ion energy fraction of $\epsilon_p \sim 0.01 - 0.1$) predicts a hard spectrum of radio emission from secondary electrons and positrons, with a detectable flux of $F_\nu \sim 1$ mJy at $\sim 100 - 300$ GHz. Higher-frequency observations can critically test the existence of the hadronic component.

5. GAMMA-RAY DETECTABILITY OF NEARBY INTERACTING SUPERNOVAE

Can we detect high-energy gamma-ray emission from nearby extragalactic SNe? For ordinary Type II SNe, the Fermi-LAT detection is possible up to a few Mpc (Murase 2018), for CSM environments suggested by SN 2013fs. Type II SNe with a much higher CSM density, which this work focuses on, are more promising targets for the purpose of detecting extragalactic SNe. In order to address this question, using SN 2010jl and SN 2014C as gamma-ray spectrum templates (see Section 4), we compare the theoretical fluxes to differential sensitivities of Fermi-LAT and Cherenkov Telescope Array (CTA). See Figure 10. For the SN 2010jl-like cases, GeV gamma-ray signal can be seen by Fermi up to $\sim 30 - 50$ Mpc, whereas detections with imaging atmospheric Cherenkov telescopes may be more difficult especially in the TeV range because of the severe gamma-ray attenuation due to the two-photon annihilation process. These features are qualitatively consistent with the previous findings by Murase et al. (2011). Note that we have used differential sensitivities, which give conservative estimates on the detectability. Indeed, the discovery horizons indicated in Figure 10 are somewhat worse than $\sim 50$ Mpc suggested from the dedicated analysis presented in Section 3. For the SN 2014C-like cases, TeV gamma-ray attenuation in the pre-shock CSM is irrelevant. Therefore, observations with ground Cherenkov telescopes will be more powerful, and CTA can detect the interacting SNe up to $\sim 5 - 8$ Mpc. The rate of Type IIn is about $\sim 7 - 9\%$ of all the core-collapse SNe (e.g., Smith et al. 2011; Li et al. 2011), and the occurrence rate of nearby Type IIn SNe within 30 Mpc is $\sim 1$ yr$^{-1}$. The rate of Type IIn SNe within 10 Mpc is thus $\sim 0.03$ yr$^{-1}$, but this value is conservative because the SN rate density within 10 Mpc is higher than the global one (Horiuchi et al. 2011). Because high-energy neutrinos from Type IIn are detectable by IceCube up to $\sim 10$ Mpc (Murase et al. 2011; Petropoulou et al. 2017), interacting SNe should be regarded as promising sources for multi-messenger observations.

6. SUMMARY

Our results are summarized as follows. (a) We numerically calculated broadband spectra of CR-induced non-thermal emission from interacting SNe, taking into account various processes such as electromagnetic cascades in the post-shock CSM as well as the attenuation in the pre-shock CSM. The electromagnetic cascade is unavoidable, although its detailed effect was not included in the previous literature (Murase et al. 2011; Zirakashvili & Ptuskin 2016; Petropoulou et al. 2016). We found that GeV gamma-ray spectra are insensitive to $s_p$ thanks to the cascade, and the attenuation effect can reduce the flux only modestly, which ensures that gamma rays can be used as a probe of shock interactions in dense environments that are difficult to directly observe in visible light, X rays, and radio waves. The phenomenological prescription we presented in this work enables us to robustly predict high-energy non-thermal signatures only with a few free parameters, given that the SN dynamics is determined by optical and X-ray observations. In the early stages of interactions, the deceleration of a fast velocity component of the SN ejecta dominates the dissipation. This enhances gamma-ray and neutrino fluxes by about one order of magnitude (Murase 2018), which can be taken into account our formalism. (b) We applied our phenomenological time-dependent model to SN IIn 2010jl, by which for the first time we derived the gamma-ray constraint on the CR energy fraction. This cannot be done without the detailed modeling of high-energy emission. In addition, we reanalyzed the Fermi-LAT data taking advantage of the new Pass 8 data release, and updated the gamma-ray limits themselves. With both theoretical and observational improvements, we obtained the new constraint on the CR energy fraction, $\epsilon_p \lesssim 0.05 - 0.1$. Within uncer-
tainties, our results are consistent with the DSA theory of CRs as well as the observations of Galactic SNRs such as Cas A, but can be regarded as intriguing constraints on the CR ion acceleration in early SNe in dense environments.

(c) We considered both hadronic and leptonic scenarios with the simplified model, and discussed the detectability of gamma-ray emission from nearby interacting SNe. High-energy gamma-ray and neutrino signals from Type IIn SNe may be observed in the near future.

(d) High-frequency radio emission from secondary electrons and positrons is a promising signature of CR ion acceleration in interacting SNe, although the CSM geometry is important for the detectability. Although detailed modeling is left for future work, our model predictions are consistent with the available radio data of SN IIn 2010jl and SN Ibn 2014C.

If the DSA theory is correct, it is natural to expect efficient acceleration of CR ions even in early stages of SNe. Particle acceleration at high-density environments has already been studied by observations of gamma rays from novae (Ackermann et al. 2014). While the SNe and novae might still share some features, the nova shock is usually slower and other physical conditions may differ from the SN case. For novae, the recent concurrent observation of optical and gamma-ray emission indicates $\epsilon_p \sim 1\%$ assuming that the optical emission is powered by the shock (Li et al. 2017). Although the gamma-ray attenuation is more important at lower-velocity shocks in general (Murase et al. 2014), such a low efficiency could be an outcome of the magnetic field perpendicular to the shock normal. However, for interacting SNe, the magnetic field geometry is highly uncertain. The shock is more powerful, and CSM eruptions would be transient, also involving shocks and turbulence. Thus, constraints or detections will help us understand the physics of the DSA as well as pre-SN mass-loss mechanisms. In addition, these are important to address the origin of CRs around or beyond the knee energy and figure out their contribution to the diffuse neutrino flux observed in IceCube (Sveshnikova 2003; Murase et al. 2014; Zirakashvili & Ptuskin 2016; Petropoulou et al. 2017). Astrophysical sources producing neutrinos via inelastic $pp$ collisions, if they significantly contribute to the diffuse neutrino flux, cannot avoid constraints from the isotropic diffuse gamma-ray background in the GeV-TeV range (Murase et al. 2013). Our results indicate SNe IIn like SN 2010jl can serve as hidden CR accelerators (Murase et al. 2016) just after the photon breakout, so they can alleviate the gamma-ray limits even though only a moderate fraction of the GeV gamma rays can be attenuated. On the other hand, SNe like SN 2014C do not suffer from the gamma-ray attenuation, so the diffuse gamma-ray background constraints can be important. High-energy emission from ordinary SNe such as Type II-P, II-L, and IIb SNe has also been predicted to be detectable for nearby SNe (Murase 2018), and our method is applicable to these objects. Future multi-messenger observations will give us important clues to this long-standing enigma of particle astrophysics.

Kohta Murase thanks Poonam Chandra, Boaz Katz, Eran Ofek, and Todd Thompson for useful discussions. We also thank internal referees in the Fermi-LAT Collaboration, especially Regina Caputo, Seth Digel, Nicola Omodei, and Nicolas Renault-Tinacci for reviewing the manuscript. The work of Kohta Murase is supported by NSF Grant No. PHY-1620777 and the Alfred P. Sloan Foundation. He also acknowledges the Hubble Fellowship through the NASA and STScI during the early stages of this work. A.F. was supported by the Initiative and Networking Fund of the Helmholtz Association. Keiichi Maeda acknowledges support by JSPS KAKENHI Grant (18H04585, 18H05223, 17H02864). J.F.B. is supported by NSF Grant No. PHY-1714479. The preliminary estimates and results were presented at the PCTS workshop at Princeton University in 2015, AMON workshop at Penn State University in 2015, and the supernova workshop at ISSI in 2016.

The Fermi-LAT Collaboration acknowledges generous ongoing support from a number of agencies and institutes that have supported both the development and the operation of the LAT as well as scientific data analysis. These include the National Aeronautics and Space Administration and the Department of Energy in the United States, the Commissariat à l’Energie Atomique and the Centre National de la Recherche Scientifique Institut National de Physique Nucléaire et de Physique des Particules in France, the Agenzia Spaziale Italiana and the Istituto Nazionale di Fisica Nucleare in Italy, the Ministry of Education, Culture, Sports, Science and Technology (MEXT), High Energy Accelerator Research Organization (KEK) and Japan Aerospace Exploration Agency (JAXA) in Japan, and the K. A. Wallenberg Foundation, the Swedish Research Council and the Swedish National Space Board in Sweden. Additional support for science analysis during the operations phase is gratefully acknowledged from the Istituto Nazionale di Astrofisica in Italy and the Centre National d’Études Spatiales in France. This work performed in part under DOE Contract DE-AC02-76SF00515.
