Abstract

Purpose

The purpose of this study was to test whether higher dissatisfaction with one's own body image, majorly than the body mass index (BMI), may be associated with higher levels of psychopathological aspects, hopelessness feelings, and psychophysical health.

Methods

Fifty-nine patients undergoing bariatric surgery filled out the Symptom Checklist-90-Revised, the Body Uneasiness Test, the 12-item Short Form Survey, the Beck Inventory Scale II, and the Beck Hopelessness Scale. Correlations and multiple regressions between measures were performed.

Results

Dissatisfaction with the perception of one's own body image was strongly correlated with a worse psychophysiological health. On the contrary, BMI showed no significant correlation with the previous variables. Furthermore, the perception of one's own body image significantly predicted the state of psychological health.

Conclusion

The findings of the present study showed a more relevant role of body image compared to the BMI in the association with psychological outcomes suggesting the importance to consider body image in the assessment and treatment of obese patients.

Introduction

Bariatric surgery is currently the gold standard for the treatment of morbid obesity and its comorbidities, leading to an improvement in psychophysical well-being [1]. Concerns about body image can significantly affect an individual with obesity and it is expected to have a negative clinical impact influencing their behaviour, quality of life and psychological health [2]. These can be some of the main motivations for weight loss in individuals with obesity [3] and a factor that motivates the decision for treatment-seeking.

Many previous studies investigated the association between the weight and the psychological aspects in obese patients. Most of the studies showed a correlation with psychological aspects as anxiety, depression, low self-confidence, alexithymia, and eating disorders in overweight and obese patients [4–8].

Furthermore, the literature focuses on the perception of one's own body image after bariatric surgery, reporting different results. One recent study [9] examined psychological well-being and body image in a sample of pre-bariatric surgery patients and in those with 1-year follow-up, showing a body image and psychological well-being improved in most patients. In general, obese patients pre or post bariatric surgery showed a clear association between body image perception and psychological state [10–13].

Instead, a recent review [14] on the goal of examining body image changes in patients with obesity pre and post bariatric surgery, shows that in most cases the perception of one's body image does not change between pre and post bariatric surgery suggesting that body image is not directly associated with the effective weight in obese patients. This could be due to a difficulty to adapt the own body image to the physical change due to the surgical intervention. Other studies reveal how obese patients can suffer from psychiatric diseases such as depression and anxiety due to a severe dissatisfaction with their body image, even after bariatric surgery [10, 11]. Furthermore, previous studies showed how body dissatisfaction seems to be correlated with hopelessness feeling in patients with normal weight [15].

The relevance of the body image is also showed by the paradox of post bariatric surgery patients where body image does not change after bariatric surgery [14]. Nevertheless, the reasons for the maintenance of an obese identity and dissatisfaction about body image, despite the weight loss, is still unclear and the studies existing in literature show the complexity of this issue (ibidem).

The aim of this study is to investigate the association between the perception of one's own body image in relation to aspects of psychophysical health in a preliminary phase of bariatric surgery. In particular, the hypothesis of this study is that a higher dissatisfaction with one's own body image, majorly than the body mass index (BMI), may be associated with higher levels of psychopathological aspects and hopelessness feelings, together with lower levels of psychophysical health.

Materials And Methods

Procedures

This study was conducted at the Bariatric Centre of Excellence IFSO-EC of "La Sapienza" University of Rome, in collaboration with the Department of Dynamic, Clinical Psychology and Health Studies of "La Sapienza" University of Rome.
The participants were recruited among patients attending the psychological assessment for bariatric surgery eligibility in the Bariatric Centre of Excellence IFSO-EC of "La Sapienza" University of Roma, between November 2020 and July 2021. Informed consent was obtained from all individual participants included in the study. The recruitment has been carried out by a trained clinical psychologist one month before surgery and the patients completed the self-reported anonymous questionnaires alone in a private room.

The exclusion criteria were (a) not being Italian citizen; (b) presence of psychopathology; (c) presence of drugs or alcohol abuse; (d) Ineligibility for surgery according to the European Guidelines on Metabolic and Bariatric Surgery [16]; (e) undergoing primary bariatric procedures. The exclusion criteria were evaluated during the preoperative psychological assessment.

This study was performed in line with the principles of the Declaration of Helsinki. Approval was granted by the Ethics Committee of University Department of Dynamic, Clinical Psychology and Health Studies of "La Sapienza" University of Rome (11/27/20, No 0001118).

**Measures**

Patients underwent an interview conducted by the clinical research psychologist where they were asked socio-demographic information such as gender, age, weight, height and BMI, marital status, education level and work status. The questionnaires administered were the following.

The Symptom Checklist-90-Revised (SCL-90-R) [17] is a widely used checklist that measures levels of psychological symptoms experienced in the past week, on a five-point Likert scale ranging from “not at all” to “extremely.” The global measures are the Global Severity Index (Global Severity Index), the Positive Symptom Total (PST) and the Positive Symptom Distress Index (PSDI). In addition, there are nine subscales describing different psychological aspects. The Italian version was used [18] and the reliability coefficients of internal consistency were good for this study (Cronbach's alpha values = .76-.87).

The Body Uneasiness Test (BUT) [19] is a self-administered questionnaire for the clinical assessment of body image disorders and related psychopathologies. It consists in two parts: BUT-A is a 34-item scale which indicates the presence of body uneasiness, and its' global measure is the Global Severity Index (BUT-A GSI) and, in addition, there are five subscale scores regarding specifics uneasiness on body image; the BUT-B is a 37-item scale assessing specific worries about body parts, shapes, or functions. The global measures are the Positive Symptom Total (BUT-PST), and the Positive Symptom Distress Index (PSDI). Also, the eight subscales subdivide different parts of the body. The validity of BUT demonstrated good internal consistency (BUT-A Cronbach's α values=.57-.88; BUT-B Cronbach's α values=.64-.88).

The 12-item Short Form Survey (SF-12) [20] is a generic quality of life (QoL) instrument that includes a subset of 12 items from the 36-item Short Form Survey. The global measure is Total Score (SF-12 Total), with the subscales of Physical Health and Mental Health. Higher scores indicate an improvement in QoL. For this study, the Italian version was used [21] and the internal consistency reliability coefficients were good (Cronbach's α value =.63).

The Beck Inventory Scale II (BDI II) [22] assesses the presence and severity of depressive symptoms. A total score above 10 is the beginning of the presence of depression. High scores show greater severity of depression. For this study, the Italian version was used [23] and it showed good internal consistency with a Cronbach coefficient α of .84.

The Beck Hopelessness Scale (BHS) [24] assesses the presence of hopelessness and negative expectations about the future, indicating the risk of suicide. It consists of 20 items in the form of yes-no questions and higher scores indicate more severe despair. For this study, the Italian version was used [25] and internal consistency was good with a Cronbach's α of .73.

**Statistical analyses**

Continuous variables (age, weight, SCL-90-R, BUT, SF-12, BDI II and BHS) are presented as mean ± standard deviation, counts or percentages. Categoric variables (sex, BMI, education level, work, and marital status) are presented as counts and percentages.

Correlational analyses (Pearson's r) between weight, BMI, BUT and the psychological outcomes were performed. Moreover, multiple regression analyses were performed including BMI, BUT-A Global Severity Index and BUT-B Positive Symptom Distress Index as predictors of psychological outcomes.

All analyses were performed with STATISTICA 8.0 software (StatSoft Inc.) and criterion for statistical significance was p < 0.05.

**Results**

A total of 59 participants were enrolled between November 2020 and July 2021. They were predominately female (n=44; 74.6%) and the average age was 39.17 years (SD = 10.11; range 19–55). Table 1 shows the participants' socio-demographic and psychological characteristics.
Table 1

Table 2
Correlational analyses (Pearson's r) among the weight, BMI and BUT with SCL-90-R, SF-90-R.
Finally, the participants in our study, obese patients undergoing bariatric surgery, showed well-defined psychological aspects in the pre-operative phase. They showed relevant to investigate the evolution of hopelessness after the bariatric surgery to identify risk factors in its increase. The fact that the participants were waiting for a bariatric surgery to solve their obesity. This expectation could influence their feelings of hopelessness. It seems that in contrast with previous studies [10,11], the present study did not show high presence of hopelessness in the obese sample. This result could be explained by the satisfaction for body image in the relationship with the psychological outcomes.

In the present study, only the dissatisfaction with body image was associated with the psychopathological outcome (BUT-A Global Severity Index and BUT-B Global Severity Index were positively correlated with all SCL-90-R scales, BDI II and BHS) with BMI, BUT-A Global Severity Index and BUT-B Positive Symptom Distress Index as predictors showed the following results. As regard to the SCL-90-R Global Severity Index, the regression model was significant, and the BUT-A Global Severity Index was a significant predictor (see Figure 1). As regard to the SCL-90-R Positive Symptom Total, the regression model was significant, and the BUT-A Global Severity Index was a significant predictor (see Figure 1). As regard to the SF-12 Physical Health, the regression model was not significant (see Figure 1). Instead, as regard to the SF-12 Mental Health, the regression model was significant, and the BUT-A Global Severity Index was a significant predictor (see Figure 1). As regard to the BDI II, the regression model was significant, and the BUT-A Global Severity Index was a significant predictor (see Figure 1). Finally, as regard to the BHS, the regression model was significant, and the BUT-A Global Severity Index was a significant predictor (see Figure 1).

### Discussion

This study investigated the association between the perception of one's own body image in relation to aspects of psychophysical health in a preliminary phase of bariatric surgery. The main finding was that a higher dissatisfaction with the perception of one's own body image was strongly associated with higher psychological symptoms and a lower psychological health. This finding is consistent with the result of a descriptive study that has investigated this kind of positive and direct relationship between the body image and the psychological well-being [26]. A higher satisfaction of one's own body image corresponds to a greater and better psychological health. This result could be explained by the fact that, due to the multidimensional and complexity of body image, there may be several factors that influence the development of a negative body image, mainly in people suffering from obesity [27]. These findings seem to support that the perception of one's own body image is not only dependent on a possible mismatch between perceived and desired body shapes, but also on the presence of mental images, emotions and thoughts that lead to associate body appearance with personal value in the social context [14]. Indeed, these people are often made fun of for their weight and appearance, the social stigma and discrimination can worsen low self-esteem and depression [28].

Another finding of the present study was that the BMI did not show any significant association with the psychopathological outcome and with quality of life. This result suggests that the effective real physical weight did not represent a risk factor per se. In fact, despite previous studies on obese patients showed strong association between the BMI and the psychopathological state [29-31], the present study showed only a few correlations between BMI and some psychological variables. Moreover, in the regression models the BMI, inserted as predictor with the two body image measures, did not show any significant effect on the psychological outcome. These findings suggest a greater relevance of the body image on the psychological state compared to the BMI. A possible explanation of this result seems to be that the experience of one's own weight is majorly related to the expectations that the individual and the others have about body image more than to the objective weight with important clinical implications. This perspective motivates the consideration of body image as a crucial variable in the outcome of interventions focused for the treatment of obesity.

In the present study, only the dissatisfaction for body image was associated with psychological outcomes (BUT-A), while the hate for a specific part of one's own body (BUT-B) showed lower grades of correlation with the psychological outcomes and when inserted in the regression models, it did not show any significant effects. This result suggests that the preoccupation for specific parts of one's own body seems to have less relevant role compared to the global dissatisfaction for body image in the relationship with the psychological outcomes.

In contrast with previous studies [10,11], the present study did not show high presence of hopelessness in the obese sample. This result could be explained by the fact that the participants were waiting for a bariatric surgery to solve their obesity. This expectation could influence their feelings of hopelessness. It seems relevant to investigate the evolution of hopelessness after the bariatric surgery to identify risk factors in its increase.

Finally, the participants in our study, obese patients undergoing bariatric surgery, showed well-defined psychological aspects in the pre-operative phase. They reported moderate and severe levels of psychological distress, especially in the somatic, obsessive-compulsive, interpersonal hypersensitivity, and depressive...
aspects. Furthermore, regarding the perception of their own body image, the participants showed a high level of discomfort, particularly on aspects related to weight phobia and preoccupation with their body image. Finally, they reported low levels of both physical and mental well-being and a mild presence of hopelessness feelings.

This is the first study that investigated the relative role of body image compared to body mass index in the association with psychological outcomes in obese patients.

This study had some limitations. The first was that self-report measures were used. The second limitation was found to be the lack of gender balance in the participant group. Finally, the sample was recruited from a single health-care centre.

What is already known on this subject?
The body image dissatisfaction is more common in people with severe obesity, particularly those who choose bariatric surgery to cure their obesity.

What does this study add?
The present study suggests a more relevant role of body image compared to the BMI in the association with psychological outcomes.
