Observational Study

Novel markers of endothelial dysfunction in hepatitis C virus-related cirrhosis: More than a mere prediction of esophageal varices

Amr Shaaban Hanafy, Mohamed Abdel Khalik Basha, Fady Maher Wadea

ORCID number: Amr Shaaban Hanafy 0000-0003-2901-2614; Mohamed Abdel Khalik Basha 0000-0002-9075-8020; Fady Maher Wadea 0000-0001-9560-8817.

Author contributions: Hanafy AS was the guarantor; Hanafy AS, and Wadea FM were involved in the study concept and design; Hanafy AS, Basha MAK, and Wadea FM participated in the acquisition, analysis, and interpretation of the data, and drafted the initial manuscript; Hanafy AS performed the statistical analysis; Basha MAK was responsible for radiological investigations; all authors revised the article critically for important intellectual content.

Institutional review board statement: The study was reviewed and approved by Zagazig Faculty of Medicine Ethical Committee.

Informed consent statement: All study participants, or their legal guardian, provided written informed consent before study enrollment.

Conflict-of-interest statement: There are no conflicts of interest to report.

Data sharing statement: No additional data are available.

Abstract

BACKGROUND
Hepatitis C virus (HCV) infection may affect lipid metabolism by enhancing the circulating levels of inflammatory cytokines, together with its impact on endothelial function.

AIM
To evaluate the potential correlation of changes in lipid profile, carotid intima-media thickness (CIMT), and ankle-brachial index with the severity of fibrosis, grades of esophageal varices (EVs), and fibrosis indices.

METHODS
The study included 240 subjects who were divided into 3 groups; group 1 (n = 90, HCV-related cirrhotic patients with EVs), group 2 (n = 90, HCV-related cirrhotic patients without EVs), and group 3 (n = 60, served as the healthy control group). All patients underwent routine laboratory tests, including a lipid profile assay. Low-density lipoproteins (LDL)/platelet count and platelet/splenic diameter ratios were calculated. Abdominal ultrasonography, CIMT by carotid Doppler, bedside ankle-brachial index (ABI), liver stiffness measurement, and upper gastrointestinal endoscopy were performed.

RESULTS
Multivariate logistic regression revealed that very-low-density lipoprotein (VLDL) (β = 0.988, odds ratio 2.5, \(P = 0.001\)), LDL/platelet count ratio (β = 1.178, odds ratio 3.24, \(P = 0.001\)), CIMT (β = 1.37, odds ratio 3.9, \(P = 0.001\)), and ABI (β = 2.3, odds ratio 5.9, \(P = 0.001\)) were the key variables associated with significant fibrosis, EVs and endothelial dysfunction. CIMT and LDL/platelet count ratio were predictive of advanced fibrosis and EVs at cutoff values of 1.1 mm and 1
INTRODUCTION

Hepatitis C virus (HCV) infection represents a major public health burden with an estimated global prevalence of 2.8% resulting in more than 185 million infected patients\(^1\). Prompt recognition of vascular changes in patients with significant liver fibrosis is required for directing therapy and follow-up against both cardiovascular disease and esophageal varices (EVs).

Chronic HCV infection is associated with a chronic inflammatory state leading to a disproportion of pro-inflammatory/anti-inflammatory cytokines ratio. Also, lipid abnormalities, insulin resistance (IR), and increased risk of atherosclerosis have been described in chronic HCV\(^2,3\).

HCV may trigger atherosclerosis through the production of intracellular adhesion molecules, anti-endothelial antibodies, oxidative stress generation, and IR\(^4,5\). Increased carotid intima-media thickness (CIMT) represents an initial ultrasonographic sign of atherosclerosis that can be easily evaluated at the bedside. Previously, HCV RNA was isolated from carotid plaques from patients infected with HCV\(^6,7\). CIMT, ABI, VLDL, LDL/platelet count ratio are good non-invasive predictors of advanced fibrosis, presence of EVs, and endothelial dysfunction in liver cirrhosis.

**Core Tip:** Hepatitis C virus (HCV) infection may affect lipid metabolism by enhancing the circulating levels of inflammatory cytokines. HCV may induce endothelial dysfunction. Carotid intima-media thickness, low-density lipoproteins (LDL)/platelet count ratio, an increase in LDL uptake by the liver accounting for the decreased serum LDL; peripheral delivery of retroviral glycoprotein E2\(^6,7\) via scavenger receptor class B member 1 protein and the LDL receptor\(^8\), the latter binds to the lipoprotein component of the viral particle or the hyper-variable region 1 of glycoprotein E2\(^8\).

HCV infection causes a defect in intrahepatic cholesterol synthesis due to its employment in viral replication, with a later decrease in the available cholesterol for peripheral delivery via VLDL and this stimulates more expression of LDL receptors and an increase in LDL uptake by the liver accounting for the decreased serum LDL; therefore, sustained virological response (SVR) may cause a rebound increase in lipid levels\(^9\). VLDL level may be low in advanced liver diseases due to decreased synthesis and therefore it can be used as a marker of advanced fibrosis\(^10\).

In addition to predicting EVs and fibrosis severity, the objective of this study was to...
determine predictive markers of vascular changes and endothelial dysfunction in HCV-related cirrhosis.

MATERIALS AND METHODS

Study aim
Evaluation of the association of changes in lipid profile, CIMT and ankle-brachial index (ABI) with the severity of fibrosis, grades of EVs, and fibrosis indices.

Study design
This cross-sectional case-control study was conducted in the Gastroenterology and Hepatology Clinic, Department of Internal Medicine, Faculty of Medicine, Zagazig University Hospitals during the period from November 2018 to December 2019. The research protocol (IRB-255-2018) was accepted by the Zagazig Faculty of Medicine Ethical Committee.

All procedures were carried out under the Zagazig University's ethical principles and in compliance with the Helsinki declaration and its more recent modifications. Informed consent was obtained from each patient who participated in the study.

Patient population
The study included chronic HCV infected patients (n = 180) and 60 healthy subjects as a control group, all were matched for age, sex, and body mass index. Diagnosis of liver cirrhosis was based on clinical, laboratory, ultrasonographic, and FibroScan features. Eligible patients obtained a diagnosis of liver cirrhosis secondary to HCV infection proven by a positive anti-HCV test and HCV-RNA in serum, and were divided into 2 groups: Group 1 which included 90 cirrhotic patients complicated with EVs and group 2 which included 90 cirrhotic patients without EVs. Group 3 included the control subjects.

Exclusion criteria
Smoking, obesity, patients with other diseases that may alter serum lipid levels such as diabetes, non-alcoholic fatty liver disease or chronic alcohol consumption, any patients who had previously received anti-viral therapy for HCV or had been cured of HCV which may induce a rebound increase in serum lipids, lipid-lowering medications, recipients of solid organ transplantation and patients who had refused to participate in the study.

Laboratory analysis
Routine laboratory tests were performed including liver and kidney function tests, full blood count, and coagulation profile. LDL-C was calculated using the Friedewald formula: 

$$\text{LDL-C (mg/dL) = Total cholesterol-(HDL-C)-(triglycerides/5)^{14}}$$

The LDL/platelet count ratio was also calculated. VLDL cholesterol was estimated by dividing the TGs/5 if the TGs were lower than 450 mg/dL^{15}.

Abdominal ultrasonography
The ultrasonographic features of liver cirrhosis or the presence of ascites were documented. Criteria for portal hypertension were defined as portal vein diameter greater than 13 mm, splenic bipolar diameter greater than 130 mm or the presence of portal venous collaterals^{16}.

Carotid artery intima-media thickness
Common carotid arteries were evaluated on both sides by an experienced radiologist who was blinded to clinical data using B-mode duplex ultrasound with a 7.5MHz linear probe (Siemens G60®). CIMT was measured from the intima lumen interface to the media adventitia interface; with a value > 0.9 mm considered abnormal. Three measures were obtained on either side; the mean CIMT was defined as the mean right and left CIMT^{17}.

Non-invasive documentation of liver fibrosis
Liver stiffness measurement: Liver stiffness measurement was performed by an experienced physician who was blinded to the clinical data of the patients using FibroScan®. Fibrosis stages F0-1; F2; F3 and F4 or cirrhosis were defined by the spectrum of liver stiffness values 2.5-7, 7.9-9.5, 9.5-12.5 and > 12.5 kPa, respectively^{18}.

**Traditional non-invasive tools**

**Fibrosis index-4:** This was calculated by the following equation using 4 factors: 
\[ \text{FIB-4} = \frac{\text{age (year) } \times \text{aspartate aminotransferase (U/L)}}{\text{platelet count (PLT) (10^9/L)} \times \text{alanine aminotransferase (U/L)}} \]. 
A fibrosis index-4 (FIB-4) score < 1.45 displayed a negative predictive value of 90% for advanced fibrosis, however, a FIB-4 > 3.25 had a 97% specificity and a positive predictive value of 65% for advanced fibrosis.\(^\text{19}\)

**PLT/splenic diameter ratio:** The PLT/splenic diameter (PLT/SD) ratio was calculated by dividing the number of platelets (μL) by the maximum bipolar diameter of the spleen in millimeters, detected by abdominal ultrasound.

**Upper gastrointestinal endoscopy**

EVs were diagnosed and graded from grade I to grade IV, using the Paquet grading system.\(^\text{20}\)

**Assessment of endothelial dysfunction**

Endothelial dysfunction can be evaluated by flow-mediated dilatation in the brachial artery using high-resolution ultrasound or simply by bedside ABI which is considered an easy and cost-effective method for assessing endothelial dysfunction.\(^\text{21}\)

The patient remained in the supine position for 5 min and the blood pressure cuff was applied to the arm and lower calf, then the stethoscope was used to measure the systolic pressure in the brachial and dorsalis pedis arteries of both sides. ABI was calculated by dividing the highest value of pressure in the dorsalis pedis arteries by the highest brachial pressure. The normal ABI is over 1 and the cutoff value to diagnose peripheral arterial disease is ≤ 0.90 at rest with a sensitivity of 95% and specificity of 100%, values > 1.40 suggest arteriosclerosis mainly seen in diabetes or chronic renal failure.\(^\text{22}\)

**Statistical analysis**

All data were statistically analyzed using SPSS 20 for Windows (SPSS Inc., Chicago, IL, United States). Quantitative data were expressed as the mean ± SD. Qualitative data were expressed as absolute frequencies (number) and (percentage). The F test was performed to compare between more than two groups of normally distributed variables. LSD with Bonferroni correction was applied to detect the difference between groups.

Spearman’s correlation coefficient (r) was performed for ordinal variables and Pearson correlation for continuous variables. Logistic regression analysis was performed by forwarding selection to identify variables independently associated with advanced fibrosis and endothelial dysfunction. All variables with \(P < 0.05\) were considered statistically significant.

Receiver operating characteristic curves were plotted and the area under the curve (AUC) was calculated, the performance of the cutoff value was judged by calculation of Youden’s J value; values near 1 indicated good performance (\(J = \text{sensitivity} + \text{specificity} – 1\)). Sensitivity/specificity and positive/negative predictive values for the non-invasive diagnosis of fibrosis, EVs, and endothelial dysfunction were assessed considering liver stiffness as the reference for stages of fibrosis.

**RESULTS**

**Basic demographic, clinical, laboratory and endoscopic findings**

The current study included 240 subjects, and the baseline demographic, laboratory, and endoscopic findings of all subjects are summarized in Table 1. A highly significant statistical difference regarding serum transaminases and platelet count was found among the groups with the key significant difference between group 1 (cirrhosis with EVs) and group 2 (cirrhosis without EVs), and group 1 (cirrhosis with EVs) and group 3 (control group) \((P = 0.001\) and 0.001, respectively).

The total cholesterol and LDL levels were significantly lower in group 1 with a significant difference between groups 1 & 2, and 1 & 3 \((P = 0.001\) and 0.001, respectively).

VLDL was significantly lower in group 1 with a significant difference between groups 1 & 2, and 1 & 3 \((P = 0.001\) and 0.001, respectively) and between group 2 & 3 \((P = 0.001\)).

Also, the LDL/platelet count ratio was significantly higher in group 1 with a significant difference between groups 1 & 2, and 1 & 3 \((P = 0.001\) and 0.001, respectively).
Table 1 Baseline laboratory and endoscopic findings of the enrolled patients

| Variable                  | Liver cirrhosis with EVs | Liver cirrhosis without EVs | Control group | P value1 |
|---------------------------|--------------------------|-----------------------------|---------------|----------|
| n                         | 90                       | 90                          | 60            | -        |
| Sex (M/F)                 | 62/28                    | 60/30                       | 40/20         | 0.4      |
| Age (yr)                  | 49.6 ± 8.4               | 47.7 ± 9.7                  | 46 ± 6.7      | 0.32     |
| BMI (kg/m²)               | 26.3 ± 2.1               | 25.8 ± 1.3                  | 26.6 ± 0.9    | 0.21     |
| ABI                       | 0.94 ± 0.09              | 1.08 ± 0.13                 | 1.16 ± 0.11   | 0.001    |
| AST (IU/L)                | 53.7 ± 10.2              | 43.7 ± 5.6                  | 31.1 ± 10.8   | 0.001    |

| EVs                       | -                        | -                           | -             | -        |
| Grade I-II, n (%)         | 32 (35.5)                | -                           | -             | -        |
| Grade III, n (%)          | 42 (46.7)                | -                           | -             | -        |
| Grade IV, n (%)           | 16 (17.8)                | -                           | -             | -        |
| 2Fundal varix, n (%)      | 12 (13.3)                | -                           | -             | -        |

1P value less than 0.05 is considered significant.
2Fundal varices were not isolated but associated with G I esophageal varices (EV) (n = 2), G II EV (n = 6), G III-IV EV (n = 4).

BMI: Body mass index; ABI: Ankle-brachial index; LDL: Low-density lipoproteins; HDL: High-density lipoproteins; VLDL: Very low-density lipoproteins; TGs: Triglycerides; EVs: Esophageal varices; AST: Aspartate aminotransferase; ALT: Alanine aminotransferase; SD: Splenic diameter; FIB-4: Fibrosis index-4.

FIB-4 values were significantly higher in group 1 with a significant difference between group 1 & 2, and 1 & 3 (P = 0.001 and 0.001, respectively) as presented in Table 1. In addition, ABI was significantly lower in group 1 when compared with group 2 and 3 (Table 1).

Radiological findings

Carotid-intima media thickness was significantly higher in group 1 when compared with group 2 and 3. These results are presented in Figure 1 and Table 2. SD and FibroScan readings (kPa) were significantly higher in cirrhotic patients with EVs with a significant difference between group 1 & 2, and 1 & 3 (P = 0.001 and 0.001), however, the PLT/SD ratio was significantly lower in the same group as presented in Table 2. The cutoff value of the PLT/SD ratio associated with advanced fibrosis and presence of EVs was 872 with a sensitivity of 100%, specificity of 94%, AUC of 0.991, P = 0.001, and Youden’s J value of 0.94.

Liver stiffness significantly correlated with platelet count (r = -0.615, P = 0.001), VLDL (r = -0.619, P = 0.001), SD (r = 0.534, P = 0.001), FIB-4 (r = 0.588, P = 0.001), CIMT (0.712, P = 0.001), LDL/PLT ratio (r = 0.677, P = 0.001), and ABI (r = -0.546, P = 0.001).
Table 2 Ultrasonographic and liver stiffness values of the enrolled patients

| Variable       | Liver cirrhosis with EVs | Liver cirrhosis without EVs | Control group | P value |
|----------------|--------------------------|-----------------------------|---------------|---------|
| Splenic diameter | 182.9 ± 21.4             | 141 ± 12.8                  | 111.2 ± 9.7   | 0.003   |
| Platelets/SD ratio | 449 ± 166                | 1374.9 ± 380                | 1701 ± 239    | 0.001   |
| FibroScan (kPa)   | 24.4 ± 6.02              | 14.8 ± 1.9                  | 5.2 ± 0.82    | 0.001   |
| CIMT (mm)        | 1.2 ± 0.13               | 0.69 ± 0.14                 | 0.62 ± 0.11   | 0.001   |

CIMT: Carotid-intima media thickness; EVs: Esophageal varices; SD: Splenic diameter.

Correlation of the new non-invasive markers to traditional tools

An increasingly significant direct correlation was detected between the LDL/PLT ratio, LS ($r = 0.677$, $P = 0.001$) and FIB4 ($r = 0.763$, $P = 0.001$). On the other hand, a high significant negative correlation was detected between VLDL and LS ($r = -0.769$, $P = 0.001$) as well as FIB4 ($r = -0.533$, $P = 0.001$) as shown in Figure 2 and Supplementary Figure 1.

Cutoff values of the new non-invasive markers for diagnostic performance for fibrosis severity, EVs and endothelial dysfunction in cirrhotic patients

Multivariate logistic regression was carried out to identify variables independently associated with fibrosis severity, EVs and endothelial dysfunction and revealed that VLDL ($\beta = 0.988$, odds ratio 2.5, $P = 0.001$), LDL/PLT ratio ($\beta = 1.178$, odds ratio 3.24, $P = 0.001$), CIMT ($\beta = 1.37$, odds ratio 3.9, $P = 0.001$), and ABI ($\beta = 2.3$, odds ratio 5.9, $P = 0.001$) were independently associated with fibrosis severity.

CIMT and LDL/PLT ratio were predictive of advanced fibrosis, EVs and endothelial dysfunction at cutoff values 1.1 mm and 1, respectively, with an AUC of 0.966 and 0.960, 95% CI (0.913-1 and 0.916-1), sensitivity of 86.9% and 94%, specificity of 95% and 82% as presented in Figure 3, and Youden’s J value = 0.819 and 0.76, respectively.

VLDL and ABI cutoff values predictive of advanced fibrosis, EVs and endothelial dysfunction were 16.5 mg/dL and 0.94 with an AUC of 0.891 and 0.823, sensitivity of 74.1% and 90.5%, and specificity of 100% and 92%, and corresponding to Youden’s J value = 0.741 and 0.82, respectively, as presented in Figure 4.

When patients were categorized based on the determined cutoff values of VLDL, CIMT, ABI, and the LDL/platelet ratio; they displayed an extremely significant discriminating ability for lipid profile, platelet count, SD, FIB-4 and the PLT/SD ratio as presented in Table 3.

CIMT > 1.1 mm, LDL/PLT ratio > 1, and VLDL < 16.5 were associated with lower ABI values and in this way endothelial dysfunction ($P = 0.001$) when compared with other non-invasive tools. Also, CIMT > 1.1 mm, LDL/PLT ratio > 1, ABI < 0.94 and VLDL < 16.5 showed comparable results for liver stiffness and were more efficient in identifying EVs ($P = 0.001$) and equally large EVs ($P = 0.048$) when compared with traditional tools such as FIB-4 and the platelets/SD ratio as shown in Table 4.
Table 3 Discriminating ability of the novel markers in the studied groups

| Variable                  | VLDL | CIMT | LDL/platelet ratio | ABI |
|---------------------------|------|------|--------------------|-----|
|                           | Cutoff value | Below 16.5 | Above 16.5 | P value | Below 1.1 | Above 1.1 | P value | Below 1 | Above 1 | P value | Below 0.94 | Above 0.94 | P value |
|                           | n    | 76   | 164               | -      | 96       | 144       | -      | 98       | 142       | -      | 70       | 170       | -      |

DISCUSSION

Compensated cirrhosis may be difficult to differentiate from chronic hepatitis. Accurate assessment of the fibrosis stage requires screening for complications mainly EVs to commence appropriate treatment.

Tools to estimate the extent and severity of liver fibrosis may be invasive such as liver biopsy, or non-invasive such as serological tests and imaging. Liver biopsy is the best available standard modality of reference, but it has some limits and it is refused by most patients.

Could endothelial dysfunction be linked to histological severity and EVs development in HCV-related cirrhosis? This was the research question in the current study.
Table 4 Performance of the novel markers when compared to the traditional tools

| Cutoff value | PLT/SD ratio above 872 | FIB-4 above 3.25 | ABI below 0.94 | LDL/PLT ratio above 1 | CIMT above 1.1 | VLDL below 16.5 | P value |

Figure 2 Correlation of liver stiffness with low-density lipoproteins/platelet count ratio (A) and very low-density lipoproteins (B). LS: Liver stiffness; LDL: Low-density lipoproteins; VLDL: Very low-density lipoproteins.

study, which revealed that cirrhotic patients with and without EVs experienced significantly more reduced levels of total cholesterol, triglycerides, LDL, VLDL and several studies determined the changes in the lipid profile of patients with chronic liver disease and correlated them with the severity of liver disease. Abbasi et al[29] stated that serum cholesterol and triglycerides levels were inversely proportional to the histological severity. Ghadir et al[30] and Boemeke et al[31] observed a significant decrease in LDL, triglyceride, VLDL, and total cholesterol in cirrhotic patients compared with controls.

In advanced cirrhosis, IR is more common and associated with dyslipidemia with enhanced systemic inflammation[32,33]. There are no available reports that link lipid profile changes, CIMT, and ABI as non-invasive tools to the presence and size of EVs.

The current study is the first to describe the capability of predicting the presence and grading of EVs using lipid profile, CIMT, and ABI and to link the emergence of
EVs with underlying endothelial dysfunction that may increase morbidity through an added cardiovascular risk.

In a study which enrolled patients with HCV and liver cirrhosis, the CIMT and epicardial fat thickness were significantly increased in the cirrhotic and non-cirrhotic HCV groups when compared with the control group, and CIMT and epicardial fat thickness were significantly increased with the progression of Child’s class, spleen span, portal vein diameter and negatively associated with PLT\cite{34}.

Another study showed that CIMT was significantly higher in HCV-positive patients (1.04) than in HCV-negative patients (0.71) with more frequent plaque formation and therefore chronic HCV was an independent risk factor for stroke\cite{35}.

Patients with chronic liver disease and cirrhosis have more elevated risks of acute coronary syndrome and peripheral arterial disease than those without chronic liver disease and cirrhosis\cite{36,37}.

In another study conducted in patients with HCV-related liver cirrhosis without a previous history of cerebrovascular disease, cardiac and peripheral vascular diseases, a decrease in the brachial-ankle pulse wave velocity was reported to be directly in proportion to the severity of cirrhosis (\(F = 4.90, P < 0.05\))\cite{38}.

Due to the proven lipid changes in cirrhotic patients and thrombocytopenia as a well-known non-invasive predictor of liver cirrhosis and EVs; a new promising non-invasive predictor (LDL/PLT ratio) was calculated, and our results confirmed that this ratio was significantly higher in cirrhotic patients complicated with EVs (\(P < 0.001\)).

Using multivariate logistic regression to detect variables independently associated with significant fibrosis, EVs, and endothelial dysfunction; CIMT, VLDL, LDL/PLT ratio, and ABI were the most significant variables.

CIMT > 1.1 mm, LDL/PLT ratio > 1, VLDL < 16.5 mg/d, and ABI < 0.94 were significantly associated with higher liver stiffness values, FIB4, SD and increased incidence of larger varices (\(P < 0.001\)) with a significant discriminating ability for the degree of liver stiffness and grades of EVs with the advantage of providing information on endothelial dysfunction assessed by ABI when they were compared with the traditional non-invasive tools such as FIB-4 and PLT/SD ratio.

The limitation of the current study is that it was conducted in a single center and specific cardiac investigations should be performed to diagnose cardiovascular disease risk such as electrocardiography, echocardiography and coronary CT angiography which need to be conducted in high risk cirrhotic patients in future studies.

**CONCLUSION**

In conclusion, based on the current results, this may offer the chance for these markers to serve as non-invasive predictors of cirrhosis, EVs and endothelial dysfunction in...
Figure 4 Receiver operating characteristic curve to detect cutoff value of ankle-brachial index (A) and very low-density lipoprotein (B). ABI: Ankle-brachial index; VLDL: Very low-density lipoprotein; AUC: Area under the curve.

this category of patients. The study raised an issue worthy of research, as patients with advanced fibrosis and larger varices had higher CIMT and lower ABI; therefore, placing these patients at an increased cardiovascular risk added to the risk of variceal bleeding; thus, prevention and treatment should be discussed in other studies.

ARTICLE HIGHLIGHTS

Research background
Hepatitis C virus (HCV) infection may affect lipid metabolism by enhancing the circulating levels of inflammatory cytokines. HCV may induce endothelial dysfunction.
Research motivation
We believe that there is a potential correlation between the changes in lipid profile, carotid intima-media thickness (CIMT) and ankle-brachial index with the severity of fibrosis, grades of esophageal varices (EVs), and fibrosis indices.

Research objectives
To identify predictive markers of vascular changes and endothelial dysfunction in HCV-related cirrhosis

Research methods
HCV infected cirrhotic patients with and without EVs were evaluated by routine laboratory tests, including lipid profile assay, abdominal ultrasonography, carotid intima-media thickness (CIMT) by carotid Doppler, bedside ankle-brachial index (ABI), liver stiffness measurement, and upper gastrointestinal endoscopy and compared to the healthy control group. Logistic regression analysis was performed to identify variables independently associated with advanced fibrosis and endothelial dysfunction.

Research results
CIMT, low-density lipoproteins (LDL)/platelet ratio, ABI, and very LDL (VLDL) were predictive of advanced fibrosis, EVs and endothelial dysfunction. They were effective at cutoff values of 1.1 mm, 1, 0.94, and 16.5 mg/dL, respectively.

Research conclusions
CIMT, ABI, VLDL, and LDL/platelet count ratio are good non-invasive predictors of advanced fibrosis, presence of EVs, and endothelial dysfunction in liver cirrhosis.

Research perspectives
The proposed markers serve as non-invasive predictors of cirrhosis, EVs and endothelial dysfunction, and patients with advanced fibrosis and larger varices had higher CIMT and lower ABI consequently, they bear an increased cardiovascular risk added to the risk of variceal bleeding. The study was designed and validated in a single-center. External, prospective validation is required to determine the widespread applicability and utility of this model.
