ABSTRACT

Autonomous systems with machine learning-based perception can exhibit unpredictable behaviors that are difficult to quantify, let alone verify. Such behaviors are convenient to capture in probabilistic models, but probabilistic model checking of such models is difficult to scale — largely due to the non-determinism added to models as a prerequisite for provable conservatism. Statistical model checking (SMC) has been proposed to address the scalability issue. However it requires large amounts of data to account for the aforementioned non-determinism, which in turn limits its scalability. This work introduces a general technique for reduction of non-determinism based on assumptions of "monotonic safety", which define a partial order between system states in terms of their probabilities of being safe. We exploit these assumptions to remove non-determinism from controller/plant models to drastically speed up probabilistic model checking and statistical model checking while providing provably conservative estimates as long as the safety is indeed monotonic. Our experiments demonstrate model-checking speed-ups of an order of magnitude while maintaining acceptable accuracy and require much less data for accurate estimates when running SMC — even when monotonic safety does not perfectly hold and provable conservatism is not achieved.

CCS CONCEPTS

• Software and its engineering → Model checking; • Theory of computation → Formal languages and automata theory.

KEYWORDS

probabilistic model checking, statistical model checking, monotonic safety

1 INTRODUCTION

Model checking is a well-established way to assure a safety-critical CPS, such as a self-driving car, by searching for violations of a safety property in the reachable states of a system model. Recent advances in perception based on machine learning (ML) have challenged model checking with unpredictable, difficult-to-model behaviors [3, 13, 31]. The uncertainties of ML-based perception and the environment where it is deployed call for probabilistic model checking (PMC) [14, 21, 29], which computes a probability that a property holds (e.g., the chance of no collisions). However, unpredictable outputs and qualitative perception errors [5], such as false negatives, can introduce complex behaviors which lead to scalability issues when performing PMC for CPS with ML components.

A common way of addressing these scalability issues is with abstractions, which simplify system models while preserving their properties of interest. For example, instead of treating a system's state space as continuous, one can grid it up into intervals, thus shrinking the size of the model and reducing the run time of probabilistic model checking. However, many abstraction techniques rely on non-determinism to ensure conservatism (e.g., one state grid cell can transition to multiple next grid cells on a given input). The model checker must then account for these non-deterministic choices, which then leads to new scalability issues.

SMC offers an alternative to PMC. SMC samples traces of a probabilistic model and uses statistical methods to obtain guarantees about the model's behavior. In the case of probabilistic models with non-determinism, this is done by employing lightweight scheduler sampling (LSS) [24]. However, LSS needs to separately sample both the probabilistic and non-deterministic behaviors of the system in question, which makes it very data hungry in the presence of large amounts of non-determinism.

To improve the scalability of PMC and data efficiency of LSS, this paper introduces a novel way to reduce non-determinism in the intermediate abstractions of models. This reduction is based on assumptions of monotonic safety (MoS) that capture our intuition about which states have a higher chance of safety than others. Encoded as partial orders, these assumptions draw on domain-specific knowledge to characterize broad safety principles in a particular system. For instance, in an obstacle-avoidance scenario, being further away from an obstacle is generally safer than being closer to it. MoS assumptions can be used to simplify models. These simplifications intent to maintain conservative safety estimates and, when MoS assumptions hold, are provably conservative. Specifically, we simplify models using MoS-driven trimming of non-deterministic transitions leading to MoS-safer states. This reduction in non-determinism speeds up PMC and improves the data efficiency of LSS.

Ultimately, MoS assumptions are heuristic and may not strictly hold in all situations: in rare cases it is worth being a little closer to the obstacle so that the perception is more accurate. Typically, it is not immediately clear where MoS holds or how to efficiently compute that MoS holds. However, we show empirically that MoS assumptions do not need to strictly hold in every state to be useful, as long as they hold most of the time.

We instantiate our MoS assumptions and MoS-driven trimming on two simulated case studies: automated braking for an autonomous vehicle and flow control of water tanks. Our MoS-driven trimming produces abstractions which estimate the safety probability of the system and are compared with standard conservative abstractions. Experiments show that our abstractions improve the scalability of PMC by an order of magnitude and the data efficiency of LSS by at least an order of magnitude. Moreover, we observe that our
abstractions remain empirically conservative, even when not provably so: they do not overestimate the chance of safety in practice, even though MoS assumptions only hold in most of the states. This paper makes three contributions: (i) a novel notion of MoS assumptions and their use for transition trimming, (ii) conservatism proofs for transition trimming under MoS assumptions, (iii) an application of MoS-trimmed abstractions to emergency braking systems and flow control in water tanks, resulting in high-performing instances of abstractions and quantifications of the MoS assumptions.

The rest of the paper is organized as follows. We introduce two complementary motivating systems in Section 2 and give the necessary formal background in Section 3. Section 4 introduces MoS assumptions. Section 5 explains how we exploit MoS assumptions to trim non-determinism from models. We describe the results of our two case studies in Section 6. The paper ends with related work (Section 7) and a conclusion (Section 8).

2 MOTIVATING SYSTEMS

Throughout the paper, we consider two systems with complementary complexities. The first one, emergency braking, has a stateless multi-output controller, a stateful temporal-output perception, and a total-order MoS in each state dimension. The second one, water tanks, has a stateless binary-output controller, a stateless multi-output perception, and a U-shaped MoS assumption.

2.1 First System: Emergency Braking

Consider an autonomous car approaching a stationary obstacle. The car is equipped with a controller which issues braking commands on detection of the obstacle and an ML-based perception system which detects obstacles. The safety goal of the car is to stop before hitting the obstacle. Following are the car dynamics, controller, and perception used in the paper.

A discrete kinematics model with time step \( \tau \) represents the velocity \( v \) and position \( d \) (same as the distance to the obstacle) of the car at time \( t \):
\[
d(t) = d(t - \tau) - r \times v(t - \tau), \quad \dot{v}(t) = v(t - \tau) - r \times b(t - \tau),
\]
where \( b(t) \) is the braking command (a.k.a. the “braking power”, BP) at time \( t \).

We use an Advanced Emergency Braking System (AEBS) [23] which uses two metrics to determine the BP: time to collide (TTC) and warning index (WI). The TTC is the amount of time until a collision if the current velocity is maintained. The WI is the amount of time until the obstacle is detected if the obstacle is not detected, no braking occurs. The BP value, \( b \), is determined by WI and TTC crossing either none, one, or both of the fixed thresholds \( C_1 \) and \( C_2 \):
\[
(WI > C_1 \land TTC > C_2) \implies b = 0
\]
\[
(WI \leq C_1 \land TTC > C_2) \lor (WI > C_1 \land TTC \leq C_2) \implies b = B_1
\]
\[
(WI \leq C_1 \land TTC \leq C_2) \implies b = B_2
\]

To detect the obstacle, the car uses the deep neural network YoloNetv3 [25], as it can run at high frequencies [27]. We say a low-level detection of the obstacle occurs when Yolo detects the obstacle. To reduce noise, we apply a majority vote filter to the low-level detections, so the AEBS receives a high-level detection with the distance to the obstacle if at least 2 of the past 3 Yolo outputs were low-level detections. We model Yolo probabilistically based on two observations. First, Yolo’s chance of detection is higher when the car is closer to the obstacle. Second, consecutive low-level detections correlate with each other due to weather conditions and similar car positions. Our perception model conditions the detection chance on the distance from the obstacle and the recent detection history.

The safety property of interest, \( \psi_{nocol} \), is the absence of a collision, specified in linear temporal logic (LTL) [26] as
\[
\psi_{nocol} := \Box (d > L),
\]
where \( L \) is the minimum allowed distance to the obstacle and is taken to be 5m. Note that in this model the car eventually stops or collides, so for any initial condition there is an upper bound on the number of time steps.

2.2 Second System: Water Tanks

Consider a system consisting of \( J \) water tanks, each of size \( TS \), draining over time and a controller that maintains some water level in each tank. With \( \omega_j(t) \) as the water level in the \( j^{th} \) tank at time \( t \), the discrete time dynamics for the water level in the tank at the next time step is given by:
\[
\omega_j(t+1) = \omega_j(t) - \text{out}_j(t) + \text{in}_j(t),
\]
where \( \text{in}_j(t) \) and \( \text{out}_j(t) \) are the amounts of water entering (“inflow”) and leaving (“outflow”) respectively the \( j^{th} \) tank at time \( t \). The inflow is determined by the controller and the outflow is a constant determined by the environment.

Each tank is equipped with ML-based perception to report its current perceived water level, \( \hat{\omega} \), which is a random function of the true current water level, \( \omega \). In the simulated system (playing the role of the reality), \( \hat{\omega} \) is determined as a positively-skewed high-variance mixture-of-gaussians error added to \( \omega \). The gaussians have higher variance for water levels in the middle of the tank and smaller variance near the edges of the tank. In addition, with constant probability the perception can output \( \hat{\omega} = 0 \) or \( \hat{\omega} = TS \) (to account for a large range of perception errors).

We model perception probabilistically as a categorical distribution of perception error, \( e \). The possible error values are integers within some \( EW \)-sized error window,
\[-EW, \ldots, -1, 0, 1, \ldots, EW,\]
plus two special values to capture unexpected outputs of ML-based perception (e.g., due to water reflections or deep network peculiarities): \( FU \) to indicate that a spurious reading of the tank being full occurred (then \( \hat{\omega} = TS \), and \( EM \) to indicate that a spurious
reading of the tank being empty occurred (then $w = 0$). Hence, this
perception model has $2EW + 3$ parameters.

The controller has a single source of water to fill one tank at a
time (or none at all) based on the perceived water levels. Then
this tank receives a constant value $in > 0$ of water, whereas the other
tanks receive $0$ water. The controller only starts filling a tank that
has water below the lower decision threshold $LT$ and stops filling
after the water reaches the upper threshold $UT$. After filling a tank
or taking one step of not filling, if the controller perceives multiple
tanks below $LT$, it starts filling the one with the least perceived
water (or, if equal, with the lowest ID $1...f$).

The safety property, $ψ_{flow}$, is that each tank must never run out
of water (i.e., $w = 0$) or overflow (i.e., $w = TS$). This property can
be expressed as the following time-bounded LTL formula:

$$ψ_{flow} := \Box [0 < w_1 < TS \land \cdots \land 0 < w_f < TS]$$

where $T$ is a fixed number of time steps within which the tanks
should be kept is the water level resulting in overflow of tanks.

3 BACKGROUND, SYSTEM MODELS, AND LSS

In the following Definitions 3.1 to 3.3, borrowed from Kwiatkowska
et al. [22], we use $\text{Dist}(S)$ to refer to the set of probability distributions
over a set $S$, $\pi_0$ as the distribution with all its probability mass
on $s \in S$, and $\mu_1 \times \mu_2$ to be the product distribution of $\mu_1$ and $\mu_2$.

Definition 3.1. A probabilistic automaton (PA) is a tuple $M =
(S, \alpha, \delta, L)$, where $S$ is a finite set of states, $\delta \in S$ is the initial state,
$\alpha$ is an alphabet of action labels, $(S, \alpha, \text{Dist}(S)) \in \delta$ is a probabilistic
transition relation, and $L : S \rightarrow 2^{AP}$ is a labeling function from
states to sets of atomic propositions from the set $AP$.

If $(s, a, \mu) \in \delta$ then the PA can make a transition in state $s$
with action label $a$ and move based on distribution $\mu$ to state $s' \in \delta$.
with probability $\mu(s')$, which is denoted by $s \stackrel{a}{\rightarrow} \mu$. If $(s, a, \eta_\delta) \in \delta$
then we say the PA can transition from state $s$ to state $s'$ via action $a$.
A state is terminal if no elements of $\delta$ contain $s$. A path in $M$ is
a finite/infinite sequence of transitions $\pi = s_0 \xrightarrow{a_1} \mu_1 s_1 \xrightarrow{a_2} \mu_2 s_2 \cdots$
with $s_0 = s$ and $\mu(s_{i+1}) > 0$. A set of paths is denoted as $\Pi$. We use
$M(s)$ to denote the PA $M$ with initial state $s$.

Reasoning about PAs also requires the notion of schedulers, which
resolve the non-determinism during an execution of a PA. For our
purposes, a scheduler $\sigma$ maps each state of the PA to an available
action label in that state. We use $\Pi_M^\sigma$ for the set of all paths through
$M$ when controlled by scheduler $\sigma$ and $Sch_M$ for the set of all schedulers
for $M$. Finally, given a scheduler $\sigma$, we define a probability
space $Pr_M^\sigma$ over the set of paths $\Pi_M^\sigma$ in the standard manner.

Given PAs $M_1$ and $M_2$, we define parallel composition as:

Definition 3.2. The parallel composition of PAs $M_1 = (S_1, \alpha_1, \delta_1, L_1)$
and $M_2 = (S_2, \alpha_2, \delta_2, L_2)$ is given by the PA $M_1 || M_2 = (S \times
S_2, (s_1, s_2), \alpha_1 \cup \alpha_2, \delta, L)$, where $L(s_1, s_2) = L_1(s_1) \cup L_2(s_2)$
and $\delta$ is such that $(s_1, s_2) \stackrel{a}{\rightarrow} \mu_1 \times \mu_2$ if one of the following holds: (i)
$s_1 \stackrel{a}{\rightarrow} \mu_1 s_2 \xrightarrow{a} \mu_2$ and $a \in \alpha_1 \cap \alpha_2$, (ii) $s_1 \stackrel{a}{\rightarrow} \mu_1 \mu_2 = \eta_\delta$s
and $a \in (\alpha_1 \setminus \alpha_2)$, (iii) $\mu_1 = \eta_{s_1}, s_2 \xrightarrow{a} \mu_2$ and $a \in (\alpha_2 \setminus \alpha_1)$.

In this paper, we are concerned with probabilities of safety prop-
erties, which we state using LTL formulas over state labels.

![Figure 1: The models of controller/plant $M_{cp}$ (left) and perception
$M_{per}$ (right) in the emergency braking system. The dashed grey
boxes indicate layers of states, with one state for each pair of dis-
tances and speeds. The red transition is probabilistic.](image)

**Definition 3.3.** For LTL formula $\psi$, PA $M$, and scheduler $\sigma \in Sch_M$, the probability of $\psi$ holding is:

$$Pr_M^\sigma(\psi) := \inf_{\sigma \in Sch_M} Pr_M^\sigma(\psi)$$

where $\pi \models \psi$ indicates that the path $\pi$ satisfies $\psi$ in the standard
LTL semantics [26]. We specifically consider LTL safety properties,
which are LTL specifications that can be falsified by a finite trace
though a model. Both $\psi_{noac}$ and $\psi_{flow}$ are LTL safety properties.

Probabilistically verifying an LTL formula $\psi$ against $M$ requires
checking that the probability of satisfying $\psi$ meets a probability
bound for all schedulers. This involves computing the minimum or
maximum probability of satisfying $\psi$ over all schedulers:

$$Pr_M^\min(\psi) := \inf_{\sigma \in Sch_M} Pr_M^\sigma(\psi)$$

$$Pr_M^\max(\psi) := \sup_{\sigma \in Sch_M} Pr_M^\sigma(\psi)$$

We call $\sigma$ a min scheduler of $M$ if $Pr_M^\sigma(\psi) = Pr_M^\min(\psi)$. We use
$Sch_M^{\min}$ to denote the set of min schedulers of $M$.

3.1 Probabilistic Automata for Motivating
Systems

We now describe how we construct the baseline PAs for the systems
described in Section 2. We always start with two models: a non-
probabilistic, discrete time, infinite state controller-plant model
$M_{cp}$ and a probabilistic perception model $M_{per}$. Our goal is to ab-
tact them as PAs and compose them so that we can analyze their
safety properties. As an illustration, we discuss our models for the
emergency braking system, shown in Figure 1. $M_{per}$ probabilistically
generates either detections or non-detections of the obstacle
and sends them to $M_{cp}$, which then selects a braking command in
response to the detection/non-detection and updates its (continuous)
distance and speed values accordingly. $M_{cp}$ then sends the
distance to the obstacle back to $M_{per}$, which it uses to alter its
detection/non-detection probabilities. We now describe how we
construct $M_{per}$ as a PA before describing how to form a standard
PA abstraction of $M_{cp}$. Note that $M_{cp}$ is not a PA since it has an
infinite number of states.

$M_{per}$ has three actions: $D$ (detection), $M$ (non-detection), dis-
tance-d (d), all of which are synchronized with $M_{cp}$. Colloquially,
we say that $M_{per}$ transmits actions $D$ and $M$ to $M_{cp}$ and $M_{cp}$
transmits parameterized action $d$ to $M_{per}$. $M_{per}$ conditions its de-
tection probabilities on both the distance $d$ and its last $W$ low-level
readings and uses a majority-vote filter over its last $N_F$ low-level
readings to determine its output of either $D$ or $M$, as described in
Section 2. The choice of low-level detection is the only probabilistic
The discrete states \( A \) are descended from the abstractions in Section 6. Determinism will be resolved when the model gets composed with reachability non-determinism gets its own unique action label from the perception values.\(^{1}\) One state in \( S \) inheritance any atomic labels \( l \) from the states in \( S_1 \) leading to labelling function \( L' \). Finally, we convert \( M_{\text{int}} \) into a PA using the tuple notation from definition Definition 3.1: \( M_{\text{int}} \rightarrow \{ S', \alpha, K \times A', \delta', L' \} \).

\(^{1}\)The size of these intervals is a modeling hyperparameter. We explore how it affects the abstractions in Section 6.

We now form our baseline model, which we also denote as \( M_{\text{int}} \), by taking \( M_{\text{per}} \mid M_{\text{int}} \). Note that the resulting model has non-determinism in its transition relation, which our MoS assumptions will aim to remove.

For the water tank system, the \( M_{\text{per}} \) and \( M_{\text{int}} \) models are constructed from equations in Section 2 in a similar fashion: \( M_{\text{per}} \) encodes the perception probabilistically and \( M_{\text{int}} \) is a PA based interval abstraction of \( M_{\text{cpl}} \) encoding the controller and plant non-probabilistically. \( M_{\text{int}} \) communicates the true water levels \((w_1 \ldots w_f)\) to \( M_{\text{per}} \) and receives the perceived water levels \((\hat{w}_1 \ldots \hat{w}_f)\). The execution terminates either when the safety property is violated or time \( T \) is reached.

### 3.2 Statistical Model Checking for PAs

This section formalizes the process of running LSS on PA \( M \) to approximate \( P_{\text{MIN}}(\psi) \). First, a set of schedulers are sampled uniformly from \( \text{Sch}_M \):

\[
\sigma_1, \ldots, \sigma_n \sim \text{Unif}(\text{Sch}_M)
\]

Then the probability of \( M \) under scheduler \( \sigma_i \), which we denote as \( p_i := P_{\text{MIN}}(\psi) \), is computed via sampling traces from the fully probabilistic model of \( M \) when scheduler \( \sigma_i \) is fixed. Finally, the smallest probability is returned: \( P_{\text{MIN}}(\psi) \triangleq \min(p_1, \ldots, p_n) \).

Since LSS relies on sampling schedulers, its output is a random variable. So consecutive runs of LSS can give different results. In addition, running LSS requires \( n \) iterations of standard statistical analysis of \( M \) with fixed schedulers. Reducing \( n \) lowers the run times of LSS, but will also give less conservative results on average. The ideal choice of \( n \) depends both on the computational resources at hand and the estimated size of the set of schedulers [\( \text{Sch}_M \)]. LSS will never output a smaller value than PMC, as \( P_{\text{MIN}}(\psi) \geq P_{\text{MIN}}(\psi) \). However, as \( n \rightarrow \infty \), \( P_{\text{MIN}}(\psi) \rightarrow 1 \), which is to say that with enough samples LSS will eventually find the smallest satisfaction probability. In practice [\( \text{Sch}_M \)] will be extremely large, thus requiring very large \( n \) to obtain reasonable safety estimates.

**Remark.** For a complete description of LSS, see [11, 24].

### 4. ASSUMPTIONS OF MONOTONIC SAFETY

This section starts by formalizing assumptions of monotonic safety (MoS) for both PMC and LSS\(^{2}\) and stating the intuitive MoS assumptions for the motivating systems. Then we observe that MoS does not always hold in practice, exemplified in our motivating systems.

**Definition 4.1 (Assumption of Monotonic Safety for PMC).** An MoS assumption for PMC is a partial order, \( \geq_{\text{MoS}} \), over the states \( S \) with respect to a given safety property \( \psi \) and a PA \( M \). It stipulates that if two states \( s_1, s_2 \) in \( S \) are ordered, \( s_1 \geq_{\text{MoS}} s_2 \), then for every scheduler \( \sigma \) of \( M \), the probability of \( M \) satisfying \( \psi \) when using scheduler \( \sigma \) and starting from state \( s_1 \) is greater or equal to the probability of \( M \) satisfying \( \psi \) when using scheduler \( \sigma \) and starting from state \( s_2 \):

\[
s_1 \geq_{\text{MoS}} s_2 \implies \forall \sigma \in \text{Sch}_M \quad P_{\text{MIN}}(\psi) \geq P_{\text{MIN}}(\psi)
\]

\(^{2}\)The two techniques require different MoS assumptions because they handle non-determinism differently.
Section 5, we present some simple counterexamples showing that to exploit MoS assumptions to reduce non-determinism in PAs in ered safer, so should be the lower speeds. Before describing how greater distance losses, and if greater distances are to be consid-

Note that assumptions of Monotonic Safety for LSS, or they could even be a full ordering over states in S. Such assumptions are to be made by the engineers familiar with the domain and the system at hand. By formalizing an MoS assumption, an engineer aims to integrate their high-level knowledge of the system’s operation into the formal analyses of this system. Several assumptions can be made for a given system, and if they do not contradict each other they can be combined into a single overarching partial order.

One way to find candidates for MoS assumptions is to examine the robustness, in terms of Signal Temporal Logic (STL) [12], of the safety property ψ. Intuitively, if state s1 is more STL-robust with respect to ψ than state s2, then it may have a higher chance of remaining safe in the subsequent execution. So one can formulate an MoS partial order based on the direction of STL robustness. However, MoS assumptions can draw on substantially broader intuitions than what can be gleaned from the safety property.

For our case studies, we consider two intuitive MoS assumptions for our emergency braking system and its safety property ψ_nocoll, and one intuitive MoS rule for our water tank system and its safety property ψ_flow. In all three rules, consider model M with different initial states s1 and s2:

- **Distance MoS ≥d**: “Increasing the distance to the obstacle does not reduce the safety chance”. That is, if M1 starts further away, i.e., d_M1 ≥ d_M2, then it is safer than M2: Pr_{M1}(ψ_nocoll) ≥ Pr_{M2}(ψ_nocoll).
- **Speed MoS ≥v**: “Decreasing the velocity does not reduce the safety chance”. That is, if M1 starts slower, i.e., v_M1 ≤ v_M2, then it is safer than M2: Pr_{M1}(ψ_nocoll) ≥ Pr_{M2}(ψ_nocoll).
- **Water level MoS ≥w**: “Moving the water level in any tank towards its middle does not reduce safety chance”. This partial order has two branches, for each half of the tank. First, if w_M1 ≥ w_M2 ≥ T_w/2, then Pr_{M1}(ψ_flow) ≥ Pr_{M2}(ψ_flow). Second, if w_M1 ≤ w_M2 ≤ T_w/2, then Pr_{M1}(ψ_flow) ≥ Pr_{M2}(ψ_flow).

Note that assumptions ≥d and ≥v, ≥w order states in the higher-robustness direction of ψ_nocoll and ψ_flow respectively. But the second AEBs assumption, ≥v, is an example of a more general rule not tied to ψ_nocoll. It was discovered by observing that higher speeds lead to greater distance losses, and if greater distances are to be considered safer, so should be the lower speeds. Before describing how to exploit MoS assumptions to reduce non-determinism in PAs in Section 5, we present some simple counterexamples showing that ≥d, ≥v, and ≥w do not always holds.

### 4.1 Violations of Monotonic Safety in the Motivating Systems

For our systems, the introduced MoS assumptions rules appear natural and intuitive: to avoid a collision, being further away and driving slower seems safer; to avoid overflowing and underflowing, it appears safer to keep the tanks half-full. As we will experimentally show in Section 6, these intuitions are mostly correct. However, our assumptions may not hold in some pairs of states, which we now demonstrate on simplified models. The proofs of these counterexamples are provided in Appendix A.

When discussing MoS scenarios in concrete systems, we consider state shifts encoded as changes to states with a state vector Δ. AEBs has two-dimensional states (d, v) and, hence, two types of shifts corresponding to ≥d and ≥v: (Δ_v > 0, 0) and (0, Δ_v < 0). Each water tank is unidimensional, so we consider scalar shifts Δ_w, such that Δ_w > 0 iff w ≤ T_w/2; otherwise, Δ_w < 0.

**Definition 4.3.** An AEBs system has distance-independent perception if the detection chance is constant: Vd, Pr_{det}(d) = q. Otherwise, it is distance-dependent.

**Definition 4.4.** An AEBs system has one BP if the controller bounds in Section 2 are infinite: C_1 = C_2 = +∞. Otherwise, it has multiple BPs.

With two counterexamples for AEBs, we demonstrate that multiple BPs or distance-dependent perception alone are sufficient to violate assumptions ≥d and ≥v. In both AEBs counterexamples, we set the time step τ = 1s and the filter window size T_F = 1.

The first counterexample shows that starting closer to the obstacle may be safer due to higher detection chances at closer distances.

**Counterexample 1.** Assumption ≥d does not hold in the AEBs with one BP and distance-independent perception for shift Δ = (1m, 0) when B = 10m/s^2, v_0 = 11m/s, d_0 = 13m, and Pr_{det}(d) = 1 − |d|/20.

The second counterexample shows that going at a faster speed may be beneficial because it leads to closer distances, which result in stronger braking.

**Counterexample 2.** Assumption ≥v does not hold in the AEBs with multiple BPs and distance-independent perception for shift Δ = (0, −1m/s) when B(d) = [10m/s^2 if d ≤ 11m; 3m/s^2 otherwise], v_0 = 9m/s, d_0 = 20m, and Pr_{det} = 0.5.

Intuitively, the above counterexamples arise when, due to distance or speed shifting, the model crosses a boundary into a different braking mode or a detection bin with a different probability.

In the water tank system, the safest state is almost never T_w/2 because of the asymmetry in in vs. out, controller choices, perception errors. Therefore, it is straightforward to upset the safety balance by picking disproportionate values for inflow and outflow.

**Definition 4.5.** A water tank system has random perception if EW = 0 and Vi = E(M_i, FU).

**Counterexample 3.** Assumption ≥w does not hold for a water tank system with J = 1, TS = 100, out = 3, in = 40, T = 4, Pr(ω = 0) = 0.4, and Pr(ω = TS) = 0.6, w = 10, and Δ_w = 30.
5 MOS-BASED TRIMMING

This section describes how we use the MoS assumptions from Section 4 to remove non-determinism from PAs to speed up PMC and LSS. The two trimming procedures are slightly different, due to the differences in how PMC and LSS handle non-determinism. Finally, recall that our MoS trimmings are only applied to the non-probabilistic transitions of the $M_{int}$ models.

5.1 MoS Abstraction for Model Checking

We describe how to remove non-determinism from a single state as follows:

Definition 5.1 (Single State PMC Transition Trimming). Let PA $M = \{S, \delta, \alpha, \delta, L\}$ with MoS assumption $\geq_{PMC}$ be given. Consider $s \in S$ and actions $\alpha_1, \alpha_2 \in \alpha$. If there exist states $s_1$ and $s_2$ such that $(s, \alpha_1, \eta_{s_1}), (s, \alpha_2, \eta_{s_2}) \in \delta$ and $s_1 \geq_{MoS} s_2$, then we return PA $M'$, which is identical to $M$ except that it does not have $(s, \alpha_1, \eta_{s_1})$ in its transition relation.

Remark. Another way to think about this trimming is that we remove every scheduler that picks $\alpha_1$ in state $s$ from $Sch_M$.

We now prove that under the MoS assumption from Definition 4.1 each application of the trimming procedure in Definition 5.1 is conservative. First, we introduce the following lemma which states that the probability of $M$ satisfying safety property $\psi$ can be decomposed by reasoning about the paths of $M$ which do and do not pass through some state $s$. The proof can be found in Appendix 3.

Lemma 5.2. Let $M$ be a PA. Assume that there are no infinite paths through $M$. Let $\psi$ be an LTL safety property. Let $\sigma$ be a scheduler of $M$ and let $s$ be a state of $M$. Then

$$Pr_M^\sigma(\psi) = Pr_M^\sigma(\psi \land \circ s) + Pr_M^\sigma(\psi \land \circ s) + Pr_M^\sigma(\psi \& \circ s)$$

We now state the single state trimming conservatism result and its proof.

Theorem 5.3 (PMC MoS and PMC Transition Trimming Implies PMC Conservatism). Let $M = \{S, \delta, \alpha, \delta, L\}$ be a PA with MoS assumption $\geq_{PMC}$. Assume that there are no infinite paths through $M$. Let $\psi$ be an LTL safety property. If we trim $M$ according to the procedure detailed in Definition 5.1 for state $s$ to arrive at model $M'$, then $Pr_M^{\min}(\psi) = Pr_{M'}^{\min}(\psi)$.

Proof. Assume that state $s$ has non-deterministic transitions to state $s_1$ via action $\alpha_1$ and state $s_2$ via action $\alpha_2$:

$$(s, \alpha_1, \eta_{s_1}), (s, \alpha_2, \eta_{s_2}) \in \delta$$

In addition, assume that $s_1 \geq_{PMC} s_2$. Now consider PA $M'$ that is formed by removing $(s, \alpha_1, \eta_{s_1})$ from $\delta$. To prove that the trimming is conservative, we just need to show that at least one minimal scheduler of $M$ for $\psi$ is contained in the set of schedulers for $M'$.

Let $\sigma$ be a minimal scheduler of $M$ for $\psi$. So $Pr_M^\sigma(\psi) = Pr_M^{\min}(\psi)$. We now show that either $\sigma$ or some other minimal scheduler is contained in the set of schedulers for $M'$ by contradiction. Assume that $\sigma \notin Sch_{M'}$. By the strong MoS assumption, $\sigma$ chooses action $\alpha_1$ in state $s$. Now consider scheduler $\sigma'$ which picks action $\alpha_2$ in state $s$ and is otherwise identical to $\sigma$. By Lemma 1, we have that:

$$Pr_{M}^\sigma(\psi) = Pr_{M}^{\sigma}(\psi \land \circ s) + Pr_{M}^\sigma(\psi \land \circ s) + Pr_{M}^\sigma(\psi \& \circ s)$$

Note that $\sigma, \sigma'$ differ only in state $s$ and $M$ has no self loops since it only has finite paths. So:

$$Pr_{M}^{\sigma}(\psi \& \circ s) = Pr_{M}^{\sigma}(\psi \& \circ s) + Pr_{M}^\sigma(\psi \& \circ s)$$

For the final two terms, we unroll one step of each of the models from state $s$ under their respective schedulers. Scheduler $\tau$ takes $M$ to state $s_1$ and $\sigma'$ takes $M$ to state $s_2$. Since $\sigma, \sigma'$ differ only in state $s$ and $M$ cannot loop back to $s$ from $s_2$, it follows that $Pr_{M}^{\sigma}(\psi) = Pr_{M}^{\sigma}(\psi)$.

Since $s_1 \geq_{MoS} s_2$ we have that:

$$Pr_{M}^{\sigma}(\psi) \geq Pr_{M}^{\sigma}(\psi) = Pr_{M}^{\sigma}(\psi)$$

It follows that $Pr_{M}^{\sigma}(\psi) \geq Pr_{M'}^{\sigma}(\psi)$. If the inequality is strict then we have a contradiction, as $\sigma$ is not a min scheduler of $M$ and if the terms are equal then both $\sigma$ and $\sigma'$ are both min schedulers and the MoS trimming preserves at least one.

The model-wide PMC MoS trimming procedure applies the trimming procedure in Definition 5.1 to all states of the model.

Corollary 5.4. The model-wide PMC MoS trimming procedure is conservative under Definition 4.1.

5.2 MoS Abstraction for Statistical Model Checking

We describe how to remove non-determinism from a single state for LSS as follows:

Definition 5.5 (Single State LSS Transition Trimming). Let $M = \{S, \delta, \alpha, \delta, L\}$ be a PA with MoS assumption $\geq_{LSS}$. Consider state $s$. Let $\alpha_1, \ldots, \alpha_d$ be the actions enabled in $s$. So $(s, \alpha_1, \eta_{s_1}), \ldots, (s, \alpha_d, \eta_{s_2}) \in \delta$ for some $s_1, \ldots, s_d \in S$. If

$$s_1 \geq_{LSS} s_2 \ldots \geq_{LSS} s_{d-1} \geq_{MoS} s_d$$

then we return PA $M'$ which is identical to $M$ except that it does not have $(s, \alpha_1, \eta_{s_1}), \ldots, (s, \alpha_d, \eta_{s_2})$ in its transition relation.

Remark. Another way to think about this trimming is that we remove every scheduler that picks $\alpha_1, \ldots, \alpha_{d-1}$ in state $s$ from $Sch_{M'}$.

We now prove under the MoS assumption from Definition 4.2 each application of the trimming procedure in Definition 5.5 is conservative. Since the LSS outputs are random variables, when we say that the results are conservative we mean that the LSS results on the untrimmed model have first order stochastic dominance (FSD) over those of the trimmed model. This is a formal way of defining that we expect $M$ to return larger safety chances than $M'$.

Definition 5.6 (First-order Stochastic Dominance (FSD)). We say that random variable $A$ has FSD over random variable $B$ if $F_A(x) \leq F_B(x) \forall x$, where $F_A(x)$ and $F_B(x)$ are the cumulative density functions (CDFs) of $A$ and $B$ at value $x$. We denote this as $A \geq FSD B$. 

Matthew Cleaveland, Ivan Ruchkin, Oleg Sokolsky, and Insup Lee
Remark. One way to think about this definition is that \( A \geq_{\text{FSD}} B \) if the probability mass of \( A \) lies to the right of that of \( B \).

We now state the single state conservatism result and give its proof.

Theorem 5.7 (LSS MoS and LSS MoS Trimming Implies LSS Conservatism). Let \( M \) be a PA with MoS assumption \( \geq_{\text{MoS}} \). Assume that there are no infinite paths through \( M \). Let \( \psi \) be an LTL safety property. If we trim \( M \) according to the procedure detailed in Definition 5.5 for state \( s \) to arrive at model \( M' \), then \( Pr_{M}^{\text{LSS},n}(\psi) \geq_{\text{FSD}} Pr_{M'}^{\text{LSS},n}(\psi) \).

Proof. Let \( s \) be a state in \( M \). Assume that state \( s \) has non-deterministic transitions to states \( s_1, s_2, \ldots, s_d \)
\[
(s, a_1, \eta_1), \ldots, (s, a_d, \eta_d) \in \delta
\]
and that:
\[
s_1 \geq_{\text{MoS}} s_2, \ldots, s_d - 1 \geq_{\text{MoS}} s_d
\]
Now consider PA \( M' \) formed by removing \((s, a_1, \eta_1), \ldots, (s, a_d, \eta_{d-1})\) from \( \delta \).

Consider scheduler \( \sigma \in \text{Sch}_M \). Now we generate its corresponding
scheduler in \( M' \), called \( \sigma' \), by requiring \( \sigma' \) to take action \( a_d \) to state \( s_d \) whenever it is in state \( s \). Effectively, we are saying that of the \( d \) choices that \( \sigma \) could make in state \( s \), \( \sigma' \) takes \( a_d \). So each \( \sigma' \in \text{Sch}_{M'} \) has \( d \) corresponding schedulers in \( \text{Sch}_M \). It follows that \( |\text{Sch}_M| = d \times |\text{Sch}_{M'}| \).

Now we show that \( Pr_{M'}^\sigma(\psi) \geq Pr_{M'}^{\sigma'}(\psi) \). By Lemma 1, we have:
\[
Pr_{M'}^{\sigma'}(\psi) = Pr_{M'}^{\sigma'}(\psi \wedge \circ s) + Pr_{M'}^{\sigma'}(os) Pr_{M'}^{\sigma'}(\psi)
\]
\[
Pr_{M'}^{\sigma'}(\psi) = Pr_{M'}^{\sigma'}(\psi \wedge \circ s) + Pr_{M'}^{\sigma'}(os) Pr_{M'}^{\sigma'}(\psi)
\]
Note that \( \sigma, \sigma' \) differ only in state \( s \) and \( M \) has no self loops since it only has finite paths. So:
\[
Pr_{M'}^{\sigma'}(\psi \wedge \circ s) = Pr_{M'}^{\sigma'}(\psi \wedge \circ s) \quad \text{and} \quad Pr_{M'}^{\sigma'}(os) = Pr_{M'}^{\sigma'}(os)
\]
For the final two terms, we unroll one step of the models from state \( s \). This one step takes model \( M \) to one of the following states:
\[
(s_1, s_2, \ldots, s_d)
\]
(determined by scheduler \( \sigma \)) and model \( M' \) to state \( s_d \) (since \( M' \) doesn’t have non-deterministic transitions to \( s_1, \ldots, s_{d-1} \)).

By \( \geq_{\text{MoS}}, Pr_{M(s_d)}^{\sigma'}(\psi) \leq Pr_{M(s_d)}^{\sigma'}(\psi) \).

Finally, since \( M, M' \) and \( \sigma \) and \( \sigma' \) differ only in state \( s \) and \( M \) cannot loop back to \( s \) from \( s_2, \ldots, s_{d-1} \), it follows that \( Pr_{M(s_d)}^{\sigma'}(\psi) \leq Pr_{M(s_d)}^{\sigma'}(\psi) \).

So:
\[
Pr_{M'}^{\sigma'}(\psi) \geq Pr_{M'}^{\sigma'}(\psi)
\]
Now draw some \( \sigma_1 \in \text{Unif}(\text{Sch}_M) \). Let \( \sigma'_1 \) be the corresponding scheduler in \( \text{sch}_{M'} \).

It follows that \( Pr_{M'}^{\sigma'_1}(\psi) = Pr_{M}^{\sigma_1}(\psi) \).

Now we apply LSS trimming to \( M \) and \( M' \).

For \( M \), we pick \( n \) schedulers uniformly \( \sigma_1, \ldots, \sigma_n \sim \text{Unif}(\text{Sch}_M) \), compute each scheduler’s safety probability \( p_i := Pr_{M}^{\sigma_i}(\psi) \) and return the smallest safety probability: \( \min_{i=1, \ldots, n}(p_i) \).

For \( M' \), we convert each \( \sigma_i \) into its corresponding \( \sigma'_i \in \text{Sch}_{M'} \), compute its safety probability \( p'_i := Pr_{M'}^{\sigma'_i}(\psi) \) and return the minimum one: \( \min_{i=1, \ldots, n}(p'_i) \).

From earlier, we know that \( p_i \geq p'_i \) for all \( i \). Therefore, it follows that \( \min_{i=1, \ldots, n}(p_i) \geq \min_{i=1, \ldots, n}(p'_i) \). So with this sample space of schedulers we always get a larger value from running LSS on \( M \) than \( M' \). Thus, the probability mass of \( Pr_{M}^{\text{LSS},n}(\psi) \) lies to the right of that of \( Pr_{M'}^{\text{LSS},n}(\psi) \). Thus, \( Pr_{M}^{\text{LSS},n}(\psi) \geq_{\text{FSD}} Pr_{M'}^{\text{LSS},n}(\psi) \).

The model-wide LSS MoS trimming procedure works by applying the trimming procedure in Definition 5.5 to all states of the model.

Corollary 5.8. The model-wide LSS MoS trimming procedure is conservative under Definition 4.2.

5.2.1 LSS Data Efficiency. As LSS is a sampling based method, it has a trade-off between sample count and accuracy. Sampling more schedulers produces more accurate LSS results. Intuitively, the larger the set of schedulers for a PA \( M \), the more schedulers LSS should sample to get a reasonable probability estimate of \( Pr_{M}^{\text{LSS},n}(\psi) \). Thus, reducing the number of schedulers when constructing \( M' \) allows LSS to sample fewer schedulers. In our evaluation, we show that our trimmings allow for better LSS results while using 10x fewer schedulers than without trimming.

6 EVALUATION AND RESULTS

Our experimental evaluation had two goals: compare the scalability/data efficiency of our abstractions and explore the extent to which Definition 4.2 holds on small models\(^1\). We perform evaluation on simulations of the two case studies described in Section 2. For PMC we use the PRISM model checker [20] and for LSS we use the MODEST model checker [2]. The code and models used can be found at: https://github.com/earnndkibbles8/I2CCPS_2022_MoS.

6.1 Setup: Data Collection and Modeling

6.1.1 AEBs. First, we set the AEBs controller in the self-driving car simulator CARLA [9], using a red Toyota Prius as the obstacle. We performed two data collections: (i) constant-\( \sigma \) runs to gather image-distance data to construct PA \( M_{\text{per}} \), (ii) AEBs-controlled runs to approximate the true value of \( Pr_{\text{necot}} \).

For the former collection, we ran 500 simulations starting from 200m and obtained 185000 pairs \((d, \theta)\). Model \( M_{\text{per}} \) contains the probabilities of detection conditioned on the 10m-wide distance bin and the past 3 low-level outcomes. For the latter collection, we ran 300 simulations of emergency braking starting at 160m and 20m/s, with YoloNet perception and a 3-wide majority filter on top. 20 runs out of 300 resulted in a crash, yielding a [0.04, 0.1] 95\% confidence interval (CI) for the true collision chance (i.e., \( 1 - Pr_{\text{necot}} \)).

6.1.2 Water Tank. To derive a probabilistic model of the simulated perception error with \( EW = 6 \), at each water level (from 1 to 7) we ran 100 trials of the perception and recorded the counts of perception errors into 15 bins, 13 of which were of width 1, representing errors from \(-6 \) to \( 6 \). Errors above 6 or below \(-6 \) got their own bins as well, which represented the perception giving an output of 0 or TS, respectively. To summarize, the model of \( M_{\text{per}} \) was a categorical distribution over the perception error with the following bins:

\[\{0, 6w - 6, 6w - 5, \ldots, 6w + 5, 6w + 6, \text{TS}\}\]

\(^1\)Large models have too many schedulers to enumerate them.
6.2 PMC Scalability and Accuracy

For each case study, we consider two different models: (i) $M_{int}$ from Section 3.1, (ii) $M_{PMC}$, which we form by applying the MoS-driven trimming procedures from Definition 5.1.

6.2.1 AEBS. One experiment evaluates the accuracy-scalability tradeoffs for a fixed initial state (160m, 20m/s) and differing distance interval sizes of the models. Figure 3 shows that $M_{PMC}$ outperforms $M_{int}$ in terms of run time while maintaining empirical conservatism. This shows that our MoS-enabled trimming shows significant speed ups while maintaining empirical conservatism, as it returns a lower safety chance than the simulations, for a range of model hyperparameters.

In the other experiment we fixed the distance interval size and varied the initial conditions, shown in Figure 4. First, $M_{int}$ scales very poorly. It takes an order of magnitude longer to run than $M_{PMC}$. Second, $M_{PMC}$ returns similar safety probabilities to $M_{int}$. Third, we computed a model using the negations of $\geq d$ and $\geq v$, which we denote as $M_{ttneg}$. This model returns very large safety probabilities. This is further evidence that $\geq d$ and $\geq v$ are fairly accurate, as taking their negations produces overly safe results.

6.2.2 Water Tank. We first fixed the initial water levels to be 50 (exactly half full) and varied the water level interval size of the models. Figure 5 shows that the $M_{PMC}$ outperforms $M_{int}$ in terms of run time while returning similar safety probabilities over a range of hyperparameters.

Figure 3: AEBs run times and safety probabilities for $M_{int}$ (green squares) and $M_{PMC}^{PMC}$ (red dots), and 95% CI for the simulated collision chance (orange band). Each dot represents a different interval size for $M_{int}$.

Figure 4: Comparison of PMC safety probabilities (left) and run times (right) for models across different initial distances and velocities of $M_{int}$ (green squares) and $M_{PMC}^{PMC}$ (red) and $M_{ttneg}^{ttneg}$ models of the AEBs example.

Figure 5: Water tank PMC run times and overflow/underflow probabilities for $M_{int}$ (green square) and $M_{PMC}^{PMC}$ (red dot). Each dot is for a set of values of a model’s hyperparameters.

6.3 LSS Data Efficiency

For each case study, we consider two different models: (i) $M_{int}$ from Section 3.1, (ii) $M_{LSS}$, which we form by applying the MoS-driven trimming procedure from Definition 5.5.

We kept the same distance and water level interval sizes as before and ran LSS on a smaller range of initial conditions for both abstractions. The safety probability of each scheduler was computed to an absolute error of 0.05 with 0.8 confidence. We ran LSS using 10 scheduler samples on both $M_{int}$ and $M_{LSS}$. In addition, we ran LSS using 1 scheduler sample on $M_{LSS}$. For all cases, we ran 10 different trials of LSS and averaged the results. The AEBs results are shown in Table 1 and Table 2 and the water tank results are shown in Figure 7. The $M_{LSS}^{LSS}$ models give more conservative safety probabilities with 10x fewer schedulers and, hence, 10x smaller run times. This is because all the extra non-determinism in the $M_{int}$ models dilutes the scheduler sampling. Note that $M_{LSS}^{LSS}$ took around the same time as $M_{int}$ when using an equal number of samples.

6.4 Validating MoS Assumptions

We generated small $M_{int}$ models for the AEBs and water tanks model and enumerated every scheduler of both. We computed the...
proportion of schedulers for which Definition 4.2 held for each pair of state pairs and the results into 
which our MoS assumptions held on these models.

6.4.1 AEBS. We kept the same discretization parameters as before and used an initial distance of 9m and speed of 1.2m/s. \( M_{\text{int}} \) had 11664 schedulers and a minimum safety chance of 0.986. \( M_{\text{PMC}}^{\text{int}} \) had a safety chance of 0.990, so our MoS-trimming is not conservative and the conjunction of \( \geq d \) and \( \geq \sigma \) does not hold. However, we want to examine how close this conjunction is to holding. So we computed each state pair involved in the MoS-trimming procedure detailed in Section 5.1, of which there were 17. Consider one such pair \( (s_1, s_2) \), with \( s_1 \geq \text{MoS} s_2 \). We then computed the safety probability of the model when starting in both \( s_1 \) and \( s_2 \) for every scheduler of the model and computed the proportion of schedulers for which \( s_1 \) gave a higher safety chance than \( s_2 \). This amounts to computing \( P_{\sigma - \text{Schm}} \left( P_{\sigma_{M(s_1)}}(\psi_{\text{hocol}}) \geq P_{\sigma_{M(s_2)}}(\psi_{\text{hocol}}) \right) \). We denote this probability as \( p_{s_1,s_2} \).

We applied this procedure to each of the 17 trimmed state pairs. For 15 of them, \( p_{s_1,s_2} = 1 \). The other two had values of 0.5 and 0.656, respectively. So \( \geq d \) and \( \geq \sigma \) hold perfectly for the majority of the state pairs. But for the pairs where it didn’t hold it was not very close to holding. This is most likely due to those two state pairs being near the AEBS control boundaries and echoes the intuitions from the counterexamples, which is that \( \geq d \) and \( \geq \sigma \) do not hold near control and perception boundaries.

6.4.2 Water Tank. We used a model of a single water tank with a max water level of 30 and the same \( T \) and water level interval size as before. \( M_{\text{int}} \) had 1024 schedulers and a minimum safety chance of 0.261. \( M_{\text{PMC}}^{\text{int}} \) had a safety chance of 0.303. So our MoS-trimming is not conservative and \( \geq w \) does not hold. However, we want to examine how close \( \geq w \) is to holding. So we computed each state pair involved in the MoS-trimming procedure from Section 5.1 used to convert \( M_{\text{int}} \) into \( M_{\text{PMC}}^{\text{int}} \), of which there were 5. Consider one such pair \( (s_1, s_2) \), with \( s_1 \geq \text{MoS} s_2 \). We then computed the safety probability of the model when starting in both \( s_1 \) and \( s_2 \) for every scheduler of the model and calculated the proportion of schedulers for which \( s_1 \) gave a higher safety chance than \( s_2 \). This amounts to computing \( P_{\sigma - \text{Schm}} \left( P_{\sigma_{M(s_1)}}(\psi_{\text{flow}}) \geq P_{\sigma_{M(s_2)}}(\psi_{\text{flow}}) \right) \).

We applied this process for each of the 5 state pairs and the results are shown in Table 3. This shows that although our MoS-trimming is not conservative, our MoS assumption \( \geq w \) holds for most schedulers and state pairs. We see that MoS holds over more schedulers near the extremes of the water tank. This also demonstrates why the MoS-trimming is so conservative for LSS, since most of the trimmed schedulers are in fact overly optimistic.

7 RELATED WORK

Many works have applied statistical analysis methods to probabilistic systems with non-determinism. As previously mentioned, [24] introduced LSS and improved upon it with smart sampling [11]. These LSS techniques have been implemented in the MODEST model checker [16]. These methods have been applied to the analysis of timed probabilistic models in [6, 17] and rare event detection [1]. Reinforcement learning techniques have also been employed to find min schedulers of markov decision processes [18].

Previous works have addressed compositional reasoning for probabilistic models, such as extending notions of simulation and bisimulation to PAs [15, 29, 30]. These relations are preserved under parallel composition, but they are too fine-grained for compositional verification. Another approach uses the notion of trace distribution inclusion (distributions over traces of automata actions) for compositional reasoning [28], but this relation is not preserved under parallel composition. Other works target more restrictive modeling formalisms than PAs, such as reactive modules [7] and probabilistic I/O systems [4]. Another work [14] automatically generates abstractions for composition. However, it forbids the composed model from having nondeterministic transitions, which does not work with the abstractions presented in this paper.

---

### Table 1: LSS Safety Probabilities for the AEBS system.

| Initial Condition (d,v) | \( M_{\text{int}} \) and 10 Schedulers | \( M_{\text{LSS}}^{\text{int}} \) and 10 Schedulers | \( M_{\text{LSS}}^{\text{PMC}} \) and 1 Scheduler |
|-------------------------|--------------------------------------|-----------------------------------------------|----------------------------------|
| (130, 14)               | 0.991                                | 0.919                                         | 0.962                            |
| (130, 18)               | 0.962                                | 0.802                                         | 0.831                            |
| (160, 14)               | 0.993                                | 0.919                                         | 0.943                            |
| (160, 18)               | 0.966                                | 0.802                                         | 0.846                            |

### Table 2: LSS Run Times (sec) for the AEBS system.

| Initial Condition (d,v) | \( M_{\text{int}} \) and 10 Schedulers | \( M_{\text{LSS}}^{\text{int}} \) and 10 Schedulers | \( M_{\text{LSS}}^{\text{PMC}} \) and 1 Scheduler |
|-------------------------|--------------------------------------|-----------------------------------------------|----------------------------------|
| (130, 14)               | 171                                  | 201                                           | 15                               |
| (130, 18)               | 603                                  | 179                                           | 11                               |
| (160, 14)               | 203                                  | 250                                           | 17                               |
| (160, 18)               | 608                                  | 228                                           | 12                               |

### Table 3: Probabilities of \( \geq w \) holding over trimmed state pairs of \( M_{\text{int}} \).

| State \( s_1 \) | State \( s_2 \) | \( p_{s_1,s_2} \) |
|----------------|----------------|-------------------|
| [5, 10]        | [0.5]          | 1.0               |
| [10, 15]       | [5, 10]        | 0.934             |
| [15, 20]       | [10, 15]       | 0.813             |

The most conceptually similar topic to our MoS assumptions is sensitivity analysis of dynamical systems, which aims to quantify how changes in system initial conditions affect system traces [8].

Reasoning about the safety of autonomous vehicles has been studied from other perspectives as well. The Responsibility-Sensitive Safety (RSS) model [19] uses physics-based safety analysis for provable safety in different driving scenarios for autonomous vehicles. RSS does not consider ML-based perception models in the closed loop of their autonomous systems. Finally, researchers have investigated the use of falsification to find perception outputs that cause unsafe system behaviors [10].

8 CONCLUSION

This paper introduced an abstraction approach for scalable probabilistic model checking and data efficient lightweight scheduler sampling of probabilistic automata. Specifically, we use intuitive assumptions of monotonic safety to remove non-determinism from PAs. When such assumptions hold, they lead to provably conservative abstractions. Even when these assumptions do not perfectly hold, MoS-based simplifications remain empirically conservative. We demonstrated these MoS-driven simplifications on case studies of a self-driving car and a water tank. Future work includes analytically bounding conservatism loss from MoS violations, extending the MoS trimming techniques to distributions of states, and exploring how our notion of MoS relate to sensitivity analysis for dynamical systems. More generally, we see the development of abstractions suitable for LSS as a promising area to explore.

APPENDIX

1 Counterexamples to Monotonic Safety in AEBS

In all counterexamples, we set $\tau = 1s$ and window size $N_F = 1$. We adopt the notation $Pr(\psi_{nocol} | d, s)$ as a shorthand for $Pr_M(d, s)(\psi_{nocol})$.

**Counterexample 1.** Assumption $\geq_d$ does not hold in the AEBS with one BP and distance-dependent perception for shift $\Delta = (1m, 0)$ when $B = 10m/s^2, v_0 = 11m/s, d_0 = 13m$, and $Pr_{det}(d) = 1 - |d|/20$.

**Proof.** We set $\delta_b = (13, 11)$ and $\delta_d = (14, 11)$. Then we calculate as follows.

$Pr_{M(\delta_a)}(\psi_{nocol}) = Pr_{det}(14) * Pr(\psi_{nocol}[3, 1] + (1 - Pr_{det}(14)) * Pr(\psi_{nocol}[3, 11] = 0)

Pr_{det}(14) * (Pr_{det}(3) * Pr(\psi_{nocol}[2, 0])

+ (1 - Pr_{det}(3)) * Pr(\psi_{nocol}[2, 1])) = Pr_{det}(2)

Pr_{det}(14) * (Pr_{det}(3) + (1 - Pr_{det}(3)) * Pr_{det}(2)) = Pr_{det}(14) * (Pr_{det}(3) * Pr_{det}(2) - Pr_{det}(3) * Pr_{det}(2)).

$Pr_{M(\delta_b)}(\psi_{nocol}) = Pr_{det}(13) * Pr(safe[2, 1] + (1 - Pr_{det}(13)) * Pr(safe[2, 11] = 0

Pr_{det}(13) * (Pr_{det}(2) * Pr(safe[1, 0])

+ (1 - Pr_{det}(2)) * Pr(safe[1, 1])) = 0

Pr_{det}(13) * Pr_{det}(2).

If we set $Pr_{det}(d) = 1 - |d|/20$ (i.e., the detection probability grows linearly from 0% at 20 meters to 100% at 0 meters), then the above falsifies MoS:

$Pr_{M(\delta_b)}(\psi_{nocol}) = 0.315 > 0.2955 = Pr_{M(\delta_a)}(\psi_{nocol})$

P.S. This inequality is reversed for less steep detection curves like $1 - |d|/40$.

The second counterexample shows that going at a faster speed may be beneficial because it leads to closer distances, which result in stronger braking.

**Counterexample 2.** Assumption $\geq_d$ does not hold in the AEBS with multiple BPs and distance-independent perception for shift $\Delta = (0, -1m/s$ when $B(d) = [10m/s^2$ if $d \leq 11m; 3m/s^2$ otherwise], $v_0 = 9m/s, d_0 = 20m$, and $Pr_{det} = 0.5$. 

(Please provide the complete content of the counterexample 2.)

Monotonic Safety for Scalable and Data-Efficient Probabilistic Safety Analysis
Proof. We set $\hat{s}_b = (20, 9)$ and $\hat{s}_a = (20, 8)$. Then we calculate as follows:

\[
\begin{align*}
Pr_{M(\hat{s}_a)}(\psi_{nocol}) &= Pr_{det} * Pr(\psi_{nocol}|11, 6) + (1 - Pr_{det}) * Pr(\psi_{nocol}|11, 9) \\
&= Pr_{det} * (Pr_{det} * Pr(\psi_{nocol}|5, 0) + (1 - Pr_{det}) * Pr(\psi_{nocol}|5, 6)) + (1 - Pr_{det}) * (Pr_{det} + Pr(\psi_{nocol}|2, 0)) = 0 \\
&+ (1 - Pr_{det}) * Pr(\psi_{nocol}|2, 9) = 0 \\
&= Pr_{det}^2 + (1 - Pr_{det}) * Pr_{det} = Pr_{det}
\end{align*}
\]

\[
\begin{align*}
Pr_{M(\hat{s}_b)}(\psi_{nocol}) &= Pr_{det} * Pr(\psi_{nocol}|12, 5) + (1 - Pr_{det}) * Pr(\psi_{nocol}|12, 8) \\
&= Pr_{det} * (Pr_{det} * Pr(\psi_{nocol}|7, 2) + (1 - Pr_{det}) * Pr(\psi_{nocol}|7, 5)) + (1 - Pr_{det}) * (Pr_{det} + Pr(\psi_{nocol}|4, 5)) = 0 \\
&+ (1 - Pr_{det}) * Pr(\psi_{nocol}|4, 8) = \cdots = 0
\end{align*}
\]

\[
\begin{align*}
Pr_{det}^2 (1 + 2Pr_{det} - 3Pr_{det}^2 + Pr_{det}^3)
\end{align*}
\]

It can be shown that for any $0 < Pr_{det} < 1$, $Pr_{det} > Pr_{det}^2 (1 + 2Pr_{det} - 3Pr_{det}^2 + Pr_{det}^3)$. For example, for $Pr_{det} = 0.5$, $0.5 > 0.34375$. Thus, the above falsifies MoS:

\[
Pr_{M(\hat{s}_b)}(\psi_{nocol}) > Pr_{M(\hat{s}_a)}(\psi_{nocol})
\]

\[\square\]

.2 Counterexamples to Monotonic Safety in Water Tanks

Counterexample 3. Assumption $\geq_w$ does not hold for a water tank system with $f = 1$, $TS = 100$, out = 3, in = 40, $T = 4$, $Pr(\hat{\omega} = 0) = 0.4$, and $Pr(\hat{\omega} = TS) = 0.6$, $w = 10$, and $\Delta_w = 30$.

Proof. For state $\hat{s}_b = 10$, we compute the chance of underflow as $0.6^3 = 0.1296$, and the chance of overflow is the chance of 3 or 4 successes in Binomial distribution $Bi(4, 0.4)$, which is 0.1792. So $Pr_{M(\hat{s}_b)}(\psi_{flow}) = 0.6912$. For state $\hat{s}_a = 40$, the chance of underflow is 0. The chance of overflow is the chance of 2+ successes in Binomial distribution from the binomial distribution $Bi(4, 0.4)$, so $Pr_{M(\hat{s}_a)}(\psi_{flow}) = 0.4752$. Thus, $\hat{s}_a \geq_w \hat{s}_b$, but $Pr_{M(\hat{s}_a)}(\psi_{flow}) < Pr_{M(\hat{s}_b)}(\psi_{flow})$. \[\square\]

.3 Proof of Trace Decomposition Lemma

Lemma 1 (Safety Probability by Trace Decomposition). Let $M$ be a PA. Assume that there are no infinite paths through $M$. Let $\sigma$ be a scheduler of $M$. Then

\[
Pr_M(\psi) = Pr_M(\psi \cup o s) + Pr_M(\psi \cup o s) Pr_M(\psi)
\]

Proof. We can split up the traces through $M$ by taking the ones that don’t pass through state $s$ and the ones that do, as these are two disjoint sets. So

\[
Pr_M(\psi) = Pr_M(\psi \cup o s) + Pr_M(\psi \cup o s)
\]

Now we examine the $Pr_M(\psi \cup o s)$ term. Note that $\psi$ is a safety property, so it can be expressed as $\square = \rho$. First, we decompose this term using the chain rule for probabilities:

\[
Pr_M(\psi \cup o s) = Pr_M(\rho \cup o s) Pr_M(\psi \cup o s)
\]

We now focus on the $Pr_M(\rho \cup o s)$. This asks for the measure of the traces which satisfy $\psi$ among the traces which pass through $s$. But by the construction of $M$ every state which falsifies $\psi$ (i.e. every state for which $\rho$ is true) is a sink state, so it is impossible for a trace through $M$ to falsify $\psi$ and then pass through $s$. Thus we have that:

\[
Pr_M(\rho \cup o s) = Pr_M(\rho)
\]

Substitute Equation (8) and Equation (9) into (7) to complete the proof.

\[\square\]
