Abstract

Diabetic retinopathy (DR) is the leading cause of blindness in adults of developed countries. Both microvasculopathy and neurodegeneration are implicated in mechanisms of DR development, with neuronal impairment preceding microvascular abnormalities, which is often underappreciated in the clinic. Most current therapeutic strategies, including anti-vascular endothelial growth factor (anti-VEGF)-antibodies, aim at treating the advanced stages (diabetic macular oedema and proliferative diabetic retinopathy) and fail to target the neuronal deterioration. Hence, new therapeutic approach(es) intended to address both vascular and neuronal impairment are urgently needed.

Hypoxia-inducible factor 1α (HIF1α) - 6-phosphofructo-2-kinase - fructose-2,6-bisphosphatase 3 (PFKFB3) pathway is critically implicated in the islet pathology of diabetes. Recent evidence highlighted the pathway relevance for pathologic angiogenesis and neurodegeneration, two key aspects in the diabetic retinopathy complication. PFKFB3 is a key to the sprouting angiogenesis along with VEGF by determining the endothelial tip-cell competition. Also, PFKFB3-driven glycolysis compromises the anti-oxidative capacity of neurons leading to neuronal loss and reactive gliosis. Therefore, the HIF1α-PFKFB3 signalling pathway is unique as being a pervasive pathological component across multiple cell types in the retina in the early as well as late stages of DR. A metabolic point-of-intervention based on HIF1α-PFKFB3 targeting thus deserves further consideration in DR.

Key words: HIF1α, PFKFB, diabetic retinopathy, angiogenesis, neurodegeneration.
Introduction

Diabetic retinopathy (DR) is the leading cause of vision loss among adults between 20 and 74 years of age in industrialised societies. A population-based study shows that one out of 12 diabetic patients over 40 years of age suffers from vision-threatening retinopathy. DR affects the neurovascular coupling in the retina. Neurovascular coupling describes the physical and biochemical relationship between the retinal neurons, glia cells, and the vascular endothelial cells (ECs), lining the eyeball’s inner surface. Inner retinal microvascular abnormalities increase vascular permeability and neovascularisation (Figure 1). These abnormalities include thickening of the vascular basement membrane, tight junction failure, pericyte loss, and formation of acellular capillaries. As a consequence, capillary occlusion and non-perfusion lead to ischaemia and trigger pathologic angiogenesis. Angiogenesis that escapes qualitative and quantitative control is the typical pathological feature of proliferative diabetic retinopathy (PDR), which is an advanced form of DR. Angiogenesis involves the outgrowth of new blood vessels from the existing vasculature in response to the reduced supply of blood/oxygen and nutrients that occur after non-perfusion and ischaemia. However, pathogenic angiogenesis also perpetually enhances ischaemia and adds to the inflammation and immune dysfunction, which are critical to PDR progression. Pro-angiogenic factors released during DR contribute directly to pathological retinal neovascularisation and to a failure to re-establish physiological control of vascular renewal. Consequently, new vessels that are formed in PDR are immature, highly permeable, and easily ruptured. The condition of these vessels leads to vitreous haemorrhages and tractional retinal detachments, which disrupt the functional orchestration of the retinal vasculature and ultimately cause vision loss.

There is growing evidence that retinal neurodegeneration precedes microvascular impairments that cannot be fully assessed by imaging methods. It was previously shown that scanning laser polarimetry and optical coherence tomography (OCT) could identify the loss of retinal ganglion cells (RGCs) concomitantly with the reduction of the nerve fibre layer thickness. This can be
advantageous given that neurodegeneration may occur in the retina in the absence of any microvascular deficit. Retinal neurodegeneration is mainly presented via neuronal apoptosis and reactive gliosis. Retinal neurodegeneration may also advance to blood-retinal barrier (BRB) breakdown and vasoregression (Figure 1). Primary mechanisms that underlie neurodegeneration in DR are considered to include extracellular glutamate accumulation (glutamate excitotoxicity), oxidative stress, imbalance between the neuroprotective and neurotrophic factors, and chronic inflammation.

To date, treatment of DR has been limited to very few therapeutic strategies aimed at controlling or containing the risk factors of progression, such as hyperglycaemia, hyperlipidaemia, and hypertension. However, the Diabetes Control and Complications Trial (DCCT) has shown that the total glycaemic exposure (HbA1c and duration of diabetes) can only account for 11% of the cumulative risk of DR, which suggests that major risk remains even after euglycaemia is established. The current therapeutic strategies are rather focused on treating the most advanced and vision-threatening states of DR. The cost-effectiveness, safety, and potential for long-term application of these therapies are controversial.

Hence, there is an unmet need for new therapeutic approach(es), especially in the early stages of DR, that are intended to target both vascular and neuronal impairments.

This review aims to illustrate the mechanisms by which the HIF1α-PFKFB3 pathway can contribute to the pathogenesis of DR and to highlight the emerging novel strategies for metabolic point-of-intervention in DR.
HIF1α-PFKFB3 signalling pathway

In our studies of islet biology in diabetes, we found that the hypoxia inducible factor 1 alpha (HIF1α) and 6-phosphofructo-2-kinase - fructose-2,6-bisphosphatase 3 (PFKFB3) signalling integrated both pseudo-hypoxic and metabolic responses to injury. HIF1α-PFKFB3 activation promoted β-cell survival at the expense of β-cell function in type 1 and type 2 diabetes 18, 19. However, HIF1α-PFKFB3 signalling has been implicated also in the control of neovascular formation 20 and neurodegeneration 21, hence potentially recapitulating the vascular and neuronal aspects of DR pathogenesis.

Several studies show that PFKFB3 can be regulated by transcriptional as well as post-transcriptional mechanisms 22. The pfkfb3 gene is located on chromosome 10p15.1 23. Its 5' promoter contains hypoxia response element (HRE) that makes pfkfb3 gene a bona fide transcriptional target of HIF1α 24. At the post-translational level, two E3 ubiquitin ligases induce PFKFB3 degradation: APC/C-Cdh1 and SKP1-CUL1-F-box protein (SCF)/β-TrCP 25, 26.

PFKFB3 is one of the bifunctional PFK2 isoenzymes (PFKFB1-4), which are ubiquitously expressed in human tissues, including the human retina 27, 28. The PFKFB3 protein is a homodimer, each monomer of which consists of two different functional domains: the N-terminal, which contains the kinase domain that is responsible for the synthesis of F2,6P2; and the C-terminal domain, which contains the bisphosphatase active site that is responsible for the degradation of F2,6P2 29. Among the four isoforms, PFKFB3 has the highest kinase to bisphosphatase activity (700-fold), and therefore this isoform promotes F2,6P2 formation. F2,6P2 allosterically activates PFK1, which is the rate-limiting enzyme of glycolysis. F2,6P2 overcomes the inhibition of PFK1 by the TCA-derived ATP, thus ultimately increasing the flux of glycolysis 30, 31.
HIF1α has been implicated in retinal microvasculopathy primarily through transcriptional activation of the critical angiogenic genes (e.g., vegf) \(^{32}\). Overactivation of VEGF signalling is essential to BRB breakdown and pathological neovascularization.

Further, PFKFB3 from the HIF1α pathway is also essential for angiogenesis by mediating the endothelial sprouting \(^{20,33}\).

HIF1α-PFKFB3 signalling appears to also play an essential role in neurodegeneration \(^{34,35}\). PFKFB3 becomes activated in response to glutamate excitotoxicity after the overstimulation of N-methyl-D-aspartate receptor (NMDAR) \(^{36-38}\), that is highly expressed in RGCs. PFKFB3-driven glycolysis is not only critical to neuronal apoptosis, but also to reactive gliosis through stimulation of unscheduled proliferation \(^{21,39}\).

### Role of ROS in DR

Reactive oxygen species (ROS) are byproducts of oxidative metabolism that act as signalling molecules in a number of physiological settings. An imbalance that results from excessive formation and/or impaired clearance of ROS leads to cytopathological consequences due to accumulation of oxidatively damaged biological macromolecules (such as DNA, proteins or lipids). The resulting oxidative stress that is instrumental in various disease states, is also considered to be a causal link between diabetes and the development of diabetic complications \(^{40-47}\).

As the retina has a high content of polyunsaturated fatty acids and the highest oxygen uptake as well as glucose oxidation relative to any other tissue, it is highly susceptible to oxidative stress \(^{48}\). Diabetic retina is marked by elevated levels of ROS such as superoxides and hydrogen peroxide, membrane lipid peroxidation \(^{49-52}\) and oxidative lesions of DNA (such as DNA adduct 8-hydroxy-2-deoxyguanosine, 8-OHdG) \(^{41,49,53}\). At the same time, levels of antioxidant enzymes superoxide dismutase (SOD), glutathione reductase, glutathione peroxidase and catalase, which scavenge free radicals, are reduced in the retina \(^{41,44}\). It is interesting that the mismatch between antioxidant
response and oxidative stress in the retina is similar to that observed in β-cells and neurons; both are characterised by a high susceptibility to excessive levels of ROS due to modest or low antioxidant defence \(^{54, 55}\). Further, once oxidative stress is initiated, it leads to accumulation of oxidatively damaged macromolecules that are responsible for progression of DR even after restoration of glycaemic control \(^{56}\). One explanation is that oxidative stress creates a self-amplifying loop through activation of the following metabolic pathways: the polyol pathway \(^{57}\), advanced glycation end-products (AGE) \(^{58}\), protein kinase C (PKC) \(^{59, 60}\), and the hexosamine biosynthesis pathway \(^{61}\), all of which are interrelated with mitochondrial overproduction of superoxide \(^{62}\).

Several transcriptional regulatory networks have evolved to leverage ROS levels to modify mitochondrial generation of ROS during stress. As such, the nuclear factor erythroid 2–related factor 2 (NRF2) directly regulates expression of HIF1A gene via antioxidant response element \(^{63}\). Apart from HIF1α role in mitochondrial ROS suppression by diverting pyruvate away from mitochondria, new evidence has emerged, which indicates that mitochondria-localised HIF1α can modify oxidative stress \(^{64}\). PFKFB3, the target of HIF1α, has been shown to undergo inhibitory posttranslational modifications to redirect the glucose metabolism towards the pentose phosphate pathway (PPP), enhancing the availability of the antioxidant systems \(^{65-67}\). However, hyperactivation of HIF1α–PFKFB3 may compromise their role in oxidative stress.

On the other hand, metabolism itself can be a target of the oxidative stress. As such, the decrease in the activity of the glycolytic enzyme glyceraldehyde 3-phosphate dehydrogenase (GAPDH) by a mechanism that involves mitochondrial overproduction of superoxide is one of the defining metabolic events upon onset of diabetes and hyperglycaemia. Mitochondrial superoxide inhibits GAPDH activity in vivo by (ADP)ribosylation of the enzyme in poly(ADP-ribose) polymerase (PARP)-dependent fashion \(^{68}\). The effect of inhibition of GAPDH can be prevented by suppression of mitochondrial superoxide by either uncoupling protein 1 (UCP-1) or by activity of manganese SOD (MnSOD) \(^{69}\). When GAPDH activity is inhibited, the levels of all glycolytic intermediates, which are upstream of GAPDH such as glyceraldehyde 3-phosphate (G3P), fructose-6-phosphate (F6P) or glucose, increase. G3P activates AGE \(^{58, 70}\) and the PKC pathway \(^{60, 71, 72}\), since the AGE precursor
methylglyoxal and PKC activator diacylglycerol are formed from G3P. Hyperglycaemia-induced methylglyoxal has been shown to cause both increased expression of the receptor for AGE-products (RAGE) and its activating ligands. In addition, the presence of pathologically activated PKC leads to increased vessel permeability and blood flow, altered recycling of growth factor receptors, stimulation of neovascularisation, endothelial proliferation and apoptosis. In contrast, mice deficient in the PKC isoform PKCβ have been found to be protected from diabetes-induced oxidative stress.

Accumulation of F6P increases the flux through the hexosamine pathway while the accumulation of glucose increases the flux through the polyol pathway. The enzyme aldose reductase reduces glucose (or G3P) thereby consuming the NADPH in the process. Recent studies confirmed GAPDH implication demonstrating that the inhibition of GAPDH activity with antisense DNA increases the activity of each of the pathways of oxidative damage to the same extent as in hyperglycaemia.

Therefore, the initial oxidative stress and the pathways that arise from glucose metabolism and that amplify ROS production seem to be highly implicated in the pathogenesis of DR.

**Role of mitochondrial dysfunction in DR**

Similar to β-cells in pancreatic islets, retina represents highly active metabolic tissue. Our group previously demonstrated that diabetogenic stress leads to mitochondrial suppression in diabetic β-cells that results in metabolic pseudo-hypoxia (suppression of mitochondria that mimics hypoxia) and activation of HIF1α-PFKFB3 pathway. As a consequence of HIF1α-PFKFB3 activation, glucose metabolism in diabetic β-cells is diverted away from mitochondria, leading to loss of glucose sensitive insulin secretion and thus β-cell function. The outcome of HIF1α activation in diabetes recapitulates previous studies in vivo utilizing mice with β-cell specific inactivation of von Hippel Lindau (Vhlh) gene that leads to HIF1α stabilization. Vhlh-deficient mice, similar to diabetic mice with high HIF1α β-cell expression, exhibit diminished mitochondrial activity and glucose-stimulated
changes in Ca^{2+} concentration, and insulin secretion. All together, these results highlight the key role of HIF1α in mitochondrial suppression in diabetes.

In diabetic retinal cells, more glucose-derived pyruvate is being oxidized, increasing the flux of electron donors (NADH and FADH2) into the electron transport chain (ETC). At the threshold of the voltage gradient, electron transfer inside complex III becomes reduced, leading to generation of superoxide. Hyperglycemia mediated ROS generation is prevented by MnSOD and/or uncoupling protein 1 (UCP-1) overexpression. However, MnSOD, together with glutathione (GSH), is being found suppressed in the diabetic and high glucose-cultured retinal mitochondria. Under this condition, endothelial cells and pericytes gradually lose their original morphological features and become heterogeneous with irregular arrangement, ultimately undergoing apoptosis. ROS-mediated damage to the mitochondrial lipid membrane results in increased activity across the permeability transition pore (PTP) in diabetic mice. Activated PTP facilitates release of cytochrome C and Bax mitochondrial membrane translocation resulting in apoptosis of the retinal capillary cells. These findings support the link between mitochondrial superoxide production and increased demise of retinal cells in high glucose environment.

The morphology of retinal mitochondria in diabetic rats resembles the predominant mitochondrial fission in response to changes of redox homeostasis in injured β-cells in diabetes. However, it seems that the mitochondrial dysfunction in the retina from DR is more pronounced. It involves damage to mitochondrial DNA (mtDNA), impaired DNA repair and mtDNA transcription which further compromises the ETC. Oxidative stress is further exacerbated by NADPH oxidase 2 (Nox2) activity and involves DNA methylation as a novel epigenetic control mechanism of cytosolic ROS production. Increased ROS levels also activate the matrix metalloproteinase 9 (MMP-9) that translocates to mitochondria, representing yet another ROS-driven pathological sequel unique to retinal mitochondria that results in the breakdown of mitochondrial membranes and apoptosis.
All together, these studies highlight the central role of mitochondrial ROS production and interrelated metabolic pathways in the early as well as late pathogenesis of progression of DR.

**Retinal glycolysis**

Glycolysis is critical for the retina to meet its energy and biogenesis demand. The prevailing oxygen-independent mode of energy generation in the presence of oxygen, known as aerobic glycolysis, dominates the energy metabolism of the retina and mimics the Warburg effect in cancer cells. Retinal cells convert 80-96% of glucose into lactate instead of directing it to the tricarboxylic acid (TCA) cycle. The gradient of aerobic glycolysis in adult retinal cells applies mainly to outer and inner retina layers because the inner retina is more dependent on oxidative phosphorylation with few exceptions, such as macroglial cells. Utilisation of aerobic glycolysis in the outer layer arises from the energy demand for the constant renewal of the photoreceptor outer segment (OS). Photoreceptors detect light from the environment and transduce it into signals in the retina. They convert most of the glucose into lactate via aerobic glycolysis to meet their high energy and biogenesis demands. A recent study used in situ hybridisation and immunochemistry to examine the phosphofructokinase-2 (PFK2) isoenzymes (one of the critical glycolytic enzymes, which are discussed below). Under the physiological conditions that prevailed in the absence of stress, photoreceptors expressed PFKFB1, PFKFB2, and PFKFB4, while PFKFB3 expression remained undetectable. However, overexpression of PFKFB3 in the adult photoreceptors affected the OS length by the increase in fructose-2,6-bisphosphate (F2,6P2). These findings suggest that PFKFB3 is not primarily involved in the aerobic glycolysis of the photoreceptors under physiological conditions. In addition, a substantial increase of aerobic glycolysis follows the progression of microvascular failure and non-perfusion during the development of DR, which may not preclude the pathological role of PFKFB3.

Although part of the inner retinal layer, macroglial cells (Müller cells and astrocytes) dominantly rely on glycolysis; Müller cells metabolise only 1% of the total glucose via oxidative phosphorylation.
This glycolysis preference originates from the fact that macroglial cells convert glucose to lactate and provide lactate as a secondary energy source to neurons \(^97\). However, the role of PFKFB3 in the retinal macroglial cells is still elusive.

Furthermore, ECs also acquire most of their energy through glycolysis rather than through oxidative phosphorylation \(^20\) (discussed below). Therefore, they form another retinal cell type that adds to the high glycolysis to oxidative phosphorylation ratio in the retina.

**HIF1α-PFKFB3 signalling activation in diabetic retinopathy**

**HIF1α signalling activation in retinopathy**

In order to maintain the continuous and delicate balance between oxygen supply and consumption, two vascular supporting systems are present in the retina: the inner retinal circulation (capillary plexuses, which are branched from the central artery of the retina) and the choroidal circulation (which nourishes the photoreceptors and the outer plexiform layer) \(^98\). The retinal vasculature adjusts continuously to minimise optical interference in the light path, which leads to a considerable oxygen tension between the retinal arteries and veins that increases retinal susceptibility to hypoxia \(^99\).

Many factors can assist the progression of retinal hypoxia in chronic hyperglycaemia. These include capillary occlusion and non-perfusion caused by an increased number of leukocytes and enhanced leukocyte adhesion \(^100\)-\(^102\), an increased number of AGEs, and oxidative stress \(^99\). Hypoxia may occur even before the retinal lesions appear, even though the total retinal blood flow seems to be increased at the early stage of DR \(^47\), \(^103\)-\(^105\).
Hypoxia-inducible factors (HIFs) are activated via post-translational stabilisation in response to hypoxia. HIFs are the transcription factors that control many aspects of the survival of tissue exposed to hypoxia, such as angiogenesis, aerobic glycolysis, cell proliferation, and inflammation. In normoxic conditions, proline residues in oxygen-dependent degradation (ODD) domain of HIF1α are hydroxylated by prolyl hydroxylases. This process leads to rapid degradation and a short half-life of HIF1α via the von Hippel-Lindau (VHL)-mediated ubiquitin-proteasome pathway. In addition, aspartic acid residues of HIF1α in the C-terminal transactivation domain (CTAD) are hydroxylated by factor-inhibiting HIF-1 (FIH-1), which blocks the binding of HIF1α to the co-activator p300/CBP (CREB-binding protein) and decreases HIF1α transcriptional activity. Under hypoxia, stabilised HIF1α binds to hypoxia-inducible factor 1β (HIF1β) (which is constitutively expressed) and forms HIF1 transcription complex, which targets multiple genes for transactivation.

Many studies have implicated HIF1α in the pathological angiogenesis and neurodegeneration of the retina in DR (Table 1). Given the transcriptional repertoire of HIF1α in hypoxia and injury, studies were performed to investigate the benefit of modifying HIF1α in retinal pathologies. Oral administration of HIF1α inhibitors have been shown to suppress significantly retinal neovascular tufts in the oxygen-induced retinopathy (OIR) model. In regard to neurodegeneration, inhibition of HIF1α improved the survival rates of RGCs and alleviated the degeneration of photoreceptors in chronic hypoxia. Specific knockout of HIF1α in Müller cells also decreased retinal vascular leakage as well as the build-up of adherent leucocytes both in OIR and in the mouse model of streptozotocin (STZ)-induced DR. Collectively, these studies indicate that HIF1α plays a crucial role in the development of the ischaemia/injury response in DR.

HIF1α directly targets more than 1,000 genes, but only a subset of these genes can be activated under hypoxia. This subset is further divided into two major categories: 1) those that increase oxygen delivery, and 2) those that decrease oxygen consumption.
**HIF1α signalling-increased oxygen delivery**

To increase oxygen delivery, HIF1α mediates angiogenesis by transcriptional activation of the key angiogenic genes, which include VEGF, C-X-C motif chemokine 12 (CXCL12), angiopoietin 2 (ANGPT2), placental growth factor (PGF), platelet-derived growth factor B (PDGFB), and erythropoietin. Chronic HIF1α-mediated VEGF transactivation leads to increased microvascular permeability of ECs under stress that can be exacerbated into the BRB breakdown and pathological neovascularisation. Activation of the vascular endothelial growth factor receptor 2 (VEGFR2) by VEGF, in turn, activates three signalling pathways: the protein kinase C (PKC), phosphatidylinositol 3-kinase (PI3K)-protein kinase B (Akt), and mitogen-activated protein kinase (MAPK)-extracellular signal-regulated kinase (ERK) pathway, which collectively contributes to the DR pathogenesis. These results encouraged the efforts to design VEGF targeting therapies. Although intravitreal injections of anti-VEGF antibodies have been used to treat DME for many years and the indications have been broadened recently to PDR, fewer than half the number of treated patients benefited from improved vision. This finding implies that functional redundancy and other factors play a role in DR progression.

Further, there are concerns that the suppression of VEGF may result in adverse effects on the survival of neurons. One study in the rat retinal ischaemia-reperfusion model has caused controversy because inhibition of VEGF-A diminished VEGF-A’s protective effects against RGC apoptosis, which was not reproduced by other studies. One explanation for the different results reported on the effect of VEGF targeting can be the context-dependent outcome of these interventions.

Further work is needed to draw conclusions on the possible adverse effects of anti-VEGF treatment on retinal neurons.
**HIF1α signalling-decreased oxygen consumption**

HIF1α remodels cell metabolism by shifting the glucose from oxidative phosphorylation to glycolysis and reducing oxygen consumption. HIF1α is potently induced by hypoxia\(^{107}\). Hypoxia can increase the flux of glucose through glycolysis in the retina. In a rat retina model under hypoxia, an accumulation of reduced mitochondrial nicotinamide adenine dinucleotide (NADH) was shown to decrease the transference of electrons and protons from cytosolic NADH to mitochondrial NAD\(^+\). This decrease led to reduced oxidative phosphorylation and the activation of phosphofructokinase (PFK), which led to increased glycolysis in both normoglycaemic and hyperglycaemic conditions\(^{127}\).

The master regulation by HIF1α is provided by transactivation of all critical glycolytic genes, such as glucose transporters (GLUTs), hexokinases (HKs), phosphofructokinases 1 (PFK1) and 2 (PFK2), pyruvate kinase muscle isozymes (PKMs), and lactate dehydrogenase A (LDHA). HIF1α also inhibits oxidative phosphorylation by up-regulation of pyruvate dehydrogenase kinase 1 (PDK1), which suppresses pyruvate dehydrogenase (PDH) and consequently leads to decreased incorporation of pyruvate into acetyl coenzyme A synthesis\(^{107}\).

In hypoxia, increased rates of glycolysis balance metabolic requirements and oxygen supply, for which reduction in oxygen consumption by HIF1α is essential.
PFKFB3 role in angiogenesis

Angiogenesis is the term for the sequence of ECs activation, tip-cell selection, sprouting, and elongation under the regulation of pro-angiogenic factors. Throughout these sequences of activation ECs adopt various metabolic states. ECs preferentially use glycolysis (about 85%) over oxidative phosphorylation to produce ATP and meet their energy demand during angiogenesis. This is due partly to the lag of the oxygen supply behind the glucose supply of the initiating tip cells and the reservation of oxygen for perivascular tissue. Besides energy, glycolysis also provides metabolic substrates. It furnishes stalk cells with carbon precursors for proliferation and generates a high level of lactate, which regulates blood flow and supplies energy for the neurons. Use of glycolysis to produce energy also protects ECs against oxidative stress arising from reactive oxygen species (ROS) during oxidative phosphorylation. Redirection of glycolysis into the PPP will increase nicotinamide adenine dinucleotide phosphate (NADPH), thus re-establishing a redox balance.

PFKFB3 has been implicated in new vessel formation. De Bock and her colleagues used different models (EC mosaic spheroids, human umbilical vein endothelial cells (HUVECs), the postnatal retina model, the OIR model, and the choroidal neovascularisation model), which revealed that PFKFB3-driven glycolysis regulated vessel sprouting in both physiological and pathological angiogenesis. After the addition of 3-(3-pyridinyl)-1-(4-pyridinyl)-2-propen-1-one (3PO), the glycolysis was decreased by 35-40%, which led to reduced EC proliferation, impaired vessel sprouting, and an amplified effect of anti-VEGFR2 monoclonal antibody. Reduced angiogenesis as a result of PFKFB3 inhibition was demonstrated in different biological and disease contexts such as pulmonary hypertension and various tumours.
PFKFB3 role in vessel sprouting

The mechanisms that underlie vessel sprouting have been studied for many years. In sprouting angiogenesis, the ECs fall into two particular subtypes, each of which executes different functions: tip cells migrate to the forefront of the vascular branch and protrude to form highly motile filopodia, while stalk cells proliferate behind tip cells and elongate the branch. ECs dynamically compete for the tip-cell position, which is continuously monitored and regulated by the VEGF-DLL4-Notch signalling (Figure 2). VEGF binds to the VEGF receptor (VEGFR) to regulate vascular function and the EC subtype specification. On the one hand, VEGF promotes the initial tip-cell expression of the Notch ligand delta-like ligand 4 (DLL4), which binds to the Notch receptor of neighbouring stalk cells. Consequently, DLL4 conducts the Notch signalling by cleavage and releasing the Notch 1 intracellular domain (NICD), which suppresses VEGFR and PFKFB3 expression in the stalk cells. On the other hand, DLL4 from the tip cells inhibits the expression of DLL4 by the stalk cells, and this process amplifies the differences between the tip and stalk cells. As a result, tip cells have a greater concentration of DLL4 and VEGF; stalk cells are subject to Notch activity. In addition, tip cells are subjected to higher glycolytic flux because of the increased PFKFB3 expression via VEGF signalling that enables tip-cell position and migration. The silencing of PFKFB3 impaired the vessel sprouting through a direct mechanism since the expression of the sprouting-related genes remained unaffected.

PFKFB3 role in BRB breakdown

PFKFB3 down-regulates the expression of vascular endothelial (VE)-cadherin, which is responsible for vessel rearrangement during sprouting. VE-cadherin is a main adherens junction protein that serves as the attachment site of the cytoskeleton and is involved in EC motility, angiogenesis, and survival.
It seems that PFKFB3-driven glycolysis is critical for ECs migration during vessel sprouting since inhibition of PFKFB3 interferes with VE-cadherin-dependent adhesion. VE-cadherin function is regulated by clathrin-dependent endocytosis, which determines the level of available VE-cadherin at the plasma membrane and adhesion strength in an ATP-dependent manner. VEGF reduces VE-cadherin-dependent adhesion, while Notch signalling has an opposing effect stimulating VE-cadherin-dependent adhesion, leading to an increase or decrease in EC migration, respectively. VE-cadherin resurfacing on the plasma membrane was depended on the PFKFB3, although it was not possible to distinguish whether this effect was caused by ATP or the independent role of PFKFB3 in the HUVEC model. Although VE-cadherin expression remained intact in this study, another study using murine ECs haplodeficient for PFKFB3 indicated the accumulation of VE-cadherin. Collectively, these studies highlighted the important role of PFKFB3 in VE-cadherin-driven ECs migration.

**PFKFB3 role in Neurodegeneration**

**PFKFB3 role in neuronal apoptosis**

RGCs are retinal neurons located in the inner retina, where they form optic nerves and provide the final common pathway for the integration and transmission of visual information from the retina to the brain. RGCs are susceptible to various types of stress, including hyperglycaemia and ischaemia/hypoxia, later related to their dependence on oxidative phosphorylation.

Increased frequency of RGC apoptosis has been reported in both animal models of diabetes and diabetic patients, indicating a potential role of hyperglycaemia in DR neurodegeneration. Nevertheless, typical mechanisms in relation to neurodegeneration in DR which may or may not involve hyperglycaemia are: 1) oxidative stress; 2) extracellular glutamate accumulation; 3) increased inflammation; and 4) decrease in neuroprotective and neurotrophic factors.
PPP flux is critical for the antioxidant defense and survival of neurons, including RGCs. Maintenance of PPP flux depends on the continuous degradation of PFKFB3 by APC/C-Cdh1. This provides the flux from glucose-6-phosphate (G6P) to 6-phosphogluconate (6PG) to be maintained at the expense of glycolytic F1,6P2. Per implication, increased levels of PFKFB3 contribute to oxidative stress with a concurrent decrease of NADPH production from PPP, ultimately leading to apoptosis in neurons and RGCs (Figure 3).

NMDAR is an ionotropic glutamate receptor that is activated by an excess of extracellular glutamate. This mechanism plays a central role in the pathogenesis of neurodegeneration in the DR, which contributes to RGC loss in both human and rat DR models. NMDAR mediated loss of primary cortical neurons may be similar to NMDAR mediated loss of RGCs in DR, converging at PFKFB3 stabilisation in APC/Cdh1 dependent fashion. Identifying PFKFB3 pathological stabilisation during NMDAR activation in the diabetic retina will inform the potential rationale for PFKFB3-based interventions.

In addition to PFKFB3, HIF1α can also lead to glutamate toxicity by increasing the release of glutamate via glutamate/aspartate transporter (GLAST) encoded by slc1a3 as demonstrated in the rodent cerebral ischaemia-reperfusion model. It is tempting to investigate if similar HIF1α dependent regulation of human SLC1A3 in the retina may contribute to glutamate excitotoxicity and neurodegeneration in DR.
PFKFB3 role in gliosis

Müller cells and astrocytes belong to macroglia cells of the retina. Unlike Müller cells, astrocytes originate from the brain and migrate to the retina along the blood vessels to build the BRB. Retinal astrocytes are mainly present at the inner surface of the retina near the optic nerve head where they wrap around blood vessels and ganglion cell axon bundles. It is believed that macroglia may contribute to DR neurodegeneration involving direct or indirect mechanisms. Macroglia uptake extracellular glutamate and convert it to glutamine, which protects neurons from glutamate excitotoxicity, while at the same time they provide them with neurotrophic factors. This interaction with neurons illustrates an indirect but important mechanism that supports neuron survival. Another indirect mechanism that increases neuronal survival via astrocyte interaction involves glycolytic metabolites, such as lactate and pyruvate. Astrocyte glycolysis preference is maintained by low APC/C-Cdh1 activity that results in stabilised expression of PFKFB3. The glycolytic mode dependent on PFKFB3 alone increases astrocyte resilience to amyloid β (Aβ) plaque formation and subsequent stress. This was demonstrated in the Alzheimer’s disease mouse model after inhibition of PFKFB3 by 1-(4-pyridinyl)-3-(2-quinolynyl)-2-propen-1-one (PFK15), clearly implicating PFKFB3 in Aβ induced gliosis.

Although some types of stress, such as ischaemic/hypoxic stress, will increase PFKFB3-driven glycolysis in astrocytes, at the same time, it is proposed that it leads to the secretion of proinflammation factors that compromise the BRB integrity. Thus, careful experimental discernment of the role of PFKFB3 in these processes is warranted in the future.

Future studies need to clarify whether dysregulation of PFKFB3 is also implicated in Müller cell-mediated gliosis and neurodegeneration.
Conclusions

Unlike physiological levels that support retinal function, excessive and/or chronic increase in the glycolytic flux contributes to aberrant angiogenesis, exposes neurons to oxidative stress due to the suppressed PPP, and increases the secretion of proinflammatory cytokines, chemokines, and neurotoxic factors, all of which collectively lead to neurodegeneration as well.

Thus, the hallmarks of DR, pathologic angiogenesis and neurodegeneration may stem from dysregulation of HIF1α-PFKFB3 pathway. The literature evidence suggests strongly that the HIF1α-PFKFB3 pathway is critical for the two key aspects of DR pathogenesis (angiogenesis and neurodegeneration) and is a common denominator of metabolic and hypoxic stress response across multiple rather than isolated cell types in the retina. Our literature review highlights the urgent need to investigate this pathway as a target for disease intersection in DR.

Figure 1. Cytopathological stages of diabetic retinopathy (DR). (left) Health. The inner blood-retinal barrier (BRB) consists of tightly connected endothelial cells (ECs) to pericytes, astrocytes, and Müller cells. Neurovascular coupling of glial cells, ECs, and neurons regulates blood flow and maintains hemodynamic stability to match the metabolic demands of the neurons. (middle) Non-proliferative DR is featured by thickening of vascular basement membrane, ECs damage with disruption of tight and adherent junctions, pericyte loss, occlusion of capillaries, and the subsequent capillary non-perfusion/ischaemia. Neurodegeneration marked by neuronal apoptosis and reactive gliosis precedes microvascular impairments, and results in BRB breakdown, vasoregression, and defective neurovascular coupling. (right) Proliferative diabetic retinopathy (PDR) manifests with pathological neovascularisation triggered by progressive retinal ischaemia. Diabetic macular oedema (DME) and PDR are the major causes of blindness in DR. GCL, ganglion cell layer; ILM, inner limiting membrane; INL, inner nuclear layer; IPL, inner plexiform layer; NFL, nerve fibre layer; OLM, outer limiting membrane; ONL, outer nuclear layer; OPL, outer plexiform layer; RPE, retinal pigment epithelium.
Figure 2. Role of HIF1α-PFKFB3 signalling in angiogenesis. (A) Retinal non-perfusion and ischaemia promote hypoxia, which activates HIF1α. HIF1α activates different angiogenic factors, including VEGF (orange dots), to increase blood reperfusion and oxygen delivery. As a HIF1α target gene, PFKFB3 is implicated in the tip cell phenotype and vessel sprouting. (B) Targeting HIF1α-PFKFB3 signalling may prevent sprouting and abnormal vessel formation. (C) HIF1α-PFKFB3 signalling and its biological mediator F2,6P2 promote tip cell competition by initiating the VEGF-DLL4-Notch signalling circuit. VEGF activates VEGFR2, which upregulates PFKFB3 levels and increases glycolysis and the expression of Notch ligand – DLL4. DLL4 binds to the Notch receptor of stalk cells, activates NICD; the latter, in turn, exerting negative feedback on VEGFR2 signalling in the stalk cells. This signalling cascade results in the glycolytic tip cells with high DLL4 and VEGF expression and less glycolytic stalk cells with high Notch signalling, directly involved in vessel sprouting. F2,6P2, fructose-2,6-biphosphate 2; FBPase1, fructose-1,6-biphosphatase 1; DLL4, delta-like ligand 4; NICD, Notch 1 intracellular domain; VEGF, vascular endothelial growth factor; VEGFR, vascular endothelial growth factor receptor.
Figure 3. HIF1α-PFKFB3 signalling in neurodegeneration. Oxidative stress and extracellular glutamate (yellow dots) accumulation are two critical mechanisms underlying neurodegeneration in diabetic retinopathy (DR). Under physiological conditions, glucose metabolism in neurons is directed to the PPP to maintain their antioxidant status. This process is accomplished by high APC/C-Cdh1 activity in neurons, in which ubiquitinated PFKFB3 is continuously degraded and its biologic mediator F2,6P2 is suppressed. During stress in DR, PFKFB3 is activated by HIF1α leading to reduced PPP. Besides, NMDAR overstimulated by extracellular glutamate accumulation inhibits APC/C-Cdh1 and upregulates PFKFB3; the latter enhances glycolytic flux, which is detrimental to neurons, thus corroborating neurodegeneration. In addition to neurons, hyperactivated astrocytes (gliosis) overexpress various proinflammatory cytokines and chemokines (blue dots), thus compromising the integrity of the blood-retinal barrier and promoting neurodegeneration. APC/C-Cdh1, anaphase-promoting complex/cyclosome; F6P, fructose-6-phosphate; F1,6P2, fructose-1,6-bisphosphate; F2,6P2, fructose-2,6-bisphosphate 2; FBPase1, fructose-1,6-bisphosphatase 1; G6P, glucose-6-phosphate; HIF1, hypoxia-inducible factor 1α transcription complex; HRE, hypoxia response element; NMDAR, N-methyl-D-aspartate receptor; PPP, pentose phosphate pathway; ROS, reactive oxygen species.
Table 1 Summary of articles that describe implication of HIF1α and/or PFKFB3 in retinopathy
