Abstract

Linear stability of inviscid, parallel, and stably stratified shear flow is studied under the assumption of smooth strictly monotonic profiles of shear flow and density, so that the local Richardson number is positive everywhere. The marginally unstable modes are systematically found by solving a one-parameter family of regular Sturm-Liouville problems, which can determine the stability boundaries more efficiently than solving the Taylor-Goldstein equation directly. By arguing for the non-existence of a marginally unstable mode, we derive new sufficient conditions for stability, which generalize the Rayleigh-Fjørtoft criterion for unstratified shear flows.

Keywords: hydrodynamic stability, stratified shear flow, Sturm-Liouville problem

1. Introduction

Instabilities of stratified shear flows are important for understanding not only geophysical phenomena but also fundamental mechanisms of flow instabilities. The couplings among vortical waves and gravity waves, which are induced by the ambient shear flow, give rise to various types of instabilities named after Kelvin, Helmholtz, Holmboe, and Taylor (see the review [1]). By replacing gravity by centrifugal force, the analogous mechanism further triggers instabil-
ities of swirling flows and vortices. The above instabilities have been described most clearly by assuming staircase profiles of the ambient vorticity and density, which enables one to interpret the instabilities in terms of the couplings of a finite number of discrete eigenmodes \[1\]. Slightly-smoothed staircase profiles are studied approximately by using matched asymptotic expansions \[2\].

However, it is generally difficult to predict and interpret the instabilities of continuous profiles because the stable disturbances occupy a continuous spectrum \[3, 4\]. Since the corresponding eigenvalue problem, called the Taylor-Goldstein equation, is non-self-adjoint and singular, the accurate stability boundary is often hard to determine both analytically and numerically. The classical Miles-Howard criterion \[4, 5\] states that the stratified shear flow is stable if the local Richardson number \( J_R \) is greater than \( 1/4 \) everywhere. Although many theoretical investigations have been made concerning various situations where \( J_R \leq 1/4 \) somewhere (see \[6, 7, 8\] and references therein), a general stability criterion for smooth profiles does not appear to be in the literature. However, a generalized version of Rayleigh-Fjortoft criterion is found when \( 0 < J_R \leq 1/4 \) everywhere in Ref. \[9\].

In this letter, we will present an efficient method for finding marginally unstable modes in the case of \( J_R > 0 \) everywhere. Following this method, we will further obtain new sufficient conditions for stability.

2. Search for Marginally Unstable Modes

We consider the linear stability of parallel shear flow \( U = (0, U(x)) \) in an inviscid, incompressible fluid of variable density \( \rho(x) \) on a domain \((x,y)\) bounded by two walls at \( x = \pm L \), where the gravitational acceleration \( g \) acts in the \(-x\) direction. By introducing the stream function of the disturbance as \( \phi(x) e^{ik(y-Ct)} \) with a complex phase speed \( C \in \mathbb{C} \) and a (real) wavenumber \( k > 0 \), stability is governed by the Taylor-Goldstein (TG) equation:

\[
\phi'' - k^2 \phi + \frac{U''}{C-U} \phi + \frac{N_B^2}{(C-U)^2} \phi = 0, \phi(\pm L) = 0, \tag{1}
\]
where the prime (') indicates the \( x \) derivative and the Boussinesq approximation 
\[ \rho(x) = \rho_0 + \delta \rho(x) \] where \( \rho_0 \gg |\delta \rho| \) has been used; \( N_B = \sqrt{-g' \rho_0} \) is the
Brunt-Väisälä (or buoyancy) frequency. If this equation has a nontrivial solution for \( C \) with a positive imaginary part, \( \text{Im} \, C > 0 \), the shear flow is spectrally unstable. In what follows, we assume a strictly increasing shear flow and a stably stratified density;

\[ U' > 0 \quad \text{and} \quad \rho' < 0 \quad \text{on } [-L, L], \] (2)

so that the local Richardson number \( J_R = N_B^2 / U'^2 \) is positive everywhere.

(Strictly decreasing shear flows \( U' < 0 \) can be treated similarly by replacing \( U \) by \( -U \) in the TG equation. In fact, a flow \( U \) is stable if and only if \( -U \) is so.)

Stability boundaries are often studied by searching for marginally unstable eigenmodes with \( C = c + i0 = \lim_{\epsilon \to +0} (c + i \epsilon) \) (where \( c = \text{Re} \, C \in \mathbb{R} \)), which were called singular neutral modes by Miles [4] because the TG equation becomes singular at the critical layer \( x_c \) satisfying \( c = U(x_c) \). Miles proved that a singular neutral mode may exist only when \( J_R(x_c) \leq 1/4 \) and only in the form of either \( \phi \propto \phi_+ \) or \( \phi \propto \phi_- \) (see the results VIII and IX of [4]), where

\[ \phi_\pm = (c + i0 - U)^{1/2 \pm \nu_c} \varphi_\pm(c, x), \] (3)

with the sign of \( \nu_c = \sqrt{1/4 - J_R(x_c)} \) delineating the two linearly independent solutions obtained by the Frobenius method. Specifically, the singularity of (3) has the following branch cuts extending to infinity,

\[ (c + i0 - U)^{1/2 \pm \nu_c} = \left| c - U \right|^{1/2 \pm \nu_c} \exp \left[ i\pi \left( \frac{1}{2} \pm \nu_c \right) H(x_c - x) \right], \] (4)

where \( H(x) \) is the Heaviside function, and \( \varphi_\pm \) are real analytic functions satisfying \( \varphi_\pm(c, x_c) \neq 0 \) as well as the boundary condition \( \varphi_\pm(c, -L) = \varphi_\pm(c, L) = 0 \). Thus, the existence of the domain \( D_w = \{ x \in [-L, L] : J_R(x) \leq 1/4 \} \) is necessary for instability, in that the singular neutral modes must have the critical layers on it. Since \( 0 \leq \nu_c < 1/2 \) for \( x_c \in D_w \), we will refer to the less singular mode \( \phi_+ \) as the “small” neutral mode, and \( \phi_- \) as the “large” neutral
mode (following the terminology of ideal MHD stability theory). Notice that these two types of neutral modes degenerate to \((c + i0 - U)^{1/2} \phi(c, x)\) only when \(J_R(x_c) = 1/4\) (which usually occurs when \(x_c\) is an endpoint of \(D_w\)). For later use, we also define \(\tilde{D}_w = \{ x \in [-L, L] : J_R(x) < 1/4 \}\) by omitting such the endpoints.

In order to find these singular neutral modes efficiently, we first apply a transformation \(\psi = (C - U)^{-1/2 + \nu_c} \phi\) to the TG equation [10] and obtain, for \(C = c + i0\),

\[
(P\psi')' - (k^2 + Q)P\psi = 0, \quad \psi(\pm L) = 0,
\]

where

\[
P(x, x_c) = [U - c]^{-2\nu_c} \exp \left[ i\pi \left( 1 - 2\nu_c \right) H(x_c - x) \right],
\]

\[
Q(x, x_c) = \left( \frac{1}{2} + \nu_c \right) \frac{U''}{U - c} - U'^2 \frac{J_R - J_R(x_c)}{(U - c)^2}.
\]

Because \(|P|^{-1}, |P|\) and \(|QP|\) are integrable functions for given \(x_c \in \tilde{D}_w\), this transformed equation is considered to be a regular Sturm-Liouville equation [13, 14], and hence \(\psi\) and \(P\psi'\) are continuous including the point \(x = x_c\). Moreover, we note from (3) that the small and large neutral modes, respectively, satisfy \(\psi_+(x_c) = 0\) and \((P\psi'_-)(x_c) = 0\) at the critical layer \(x_c \in \tilde{D}_w\). Base on this fact, we divide the domain into \([-L, x_c]\) and \([x_c, L]\), and seek the small and large solutions on each side as follows. By introducing the operator,

\[
\mathcal{E}(x_c, \lambda)\psi := (|P|\psi')' - (\lambda + Q)|P|\psi,
\]

that depends on the parameter \(\lambda = k^2 > 0\), we solve

\[
\mathcal{E}(x_c, \lambda_L+)\psi = 0, \quad \psi(-L) = 0, \quad \psi(x_c) = 0, \quad \psi'(x_c) = 0,
\]

\[
\mathcal{E}(x_c, \lambda_L-)\psi = 0, \quad \psi(-L) = 0, \quad (|P|\psi')(x_c) = 0,
\]

on \([-L, x_c]\) and

\[
\mathcal{E}(x_c, \lambda_R+)\psi = 0, \quad \psi(L) = 0, \quad \psi(x_c) = 0, \quad \psi'(x_c) = 0,
\]

\[
\mathcal{E}(x_c, \lambda_R-)\psi = 0, \quad \psi(L) = 0, \quad (|P|\psi')(x_c) = 0,
\]

on \([x_c, L]\).
on \([x_c, L]\). Because each of (7)-(10) is a regular Sturm-Liouville problem with either Dirichlet or Neumann boundary condition at \(x = x_c\), Sturm’s oscillation theorem \([13]\) guarantees that the eigenvalues can be ordered as follows.

\[
\infty > \lambda_{L-}^{(1)} > \lambda_{L+}^{(1)} > \lambda_{L-}^{(2)} > \lambda_{L+}^{(2)} > \lambda_{L-}^{(3)} > \cdots \rightarrow -\infty,
\]
\[
\infty > \lambda_{R-}^{(1)} > \lambda_{R+}^{(1)} > \lambda_{R-}^{(2)} > \lambda_{R+}^{(2)} > \lambda_{R-}^{(3)} > \cdots \rightarrow -\infty,
\]

where the superscript \((n)\) indicates the \(n\)th largest eigenvalue. Here, only a finite number of positive eigenvalues is of our interest (since \(\lambda = k^2 > 0\)) and these eigenvalues depend on \(x_c \in \hat{D}_w\) continuously. Again at the endpoints \(x_c \in D_w \setminus \hat{D}_w\) (namely, \(J_R(x_c) = 1/4\)), the degeneracy, \(\lambda_{L-}^{(n)} = \lambda_{L+}^{(n)}\) and \(\lambda_{R-}^{(n)} = \lambda_{R+}^{(n)}\) \((n = 1, 2, \ldots)\), must occur. If the matching condition \(\lambda_{L-} = \lambda_{R-} > 0\) between the left and right domains is satisfied for a specific \(x_c \in D_w\), there is a large neutral mode \(\psi_-\) for such \(c = U(x_c)\) and \(k = \sqrt{\lambda_{L-}} = \sqrt{\lambda_{R-}}\). Similarly, there exists a small neutral mode \(\psi_+\) if \(\lambda_{L+} = \lambda_{R+} > 0\) occurs for a specific \(x_c \in D_w\).

We have applied this approach numerically to the following three examples:

(i) \(U = \tanh(10x), N_B^2 = 22\),

(ii) \(U = x, N_B^2 = 0.1 + 10x^2\),

(iii) \(U = \tanh(10x), N_B^2 = 30/(1 + 10^4x^2)\),

on the common domain \([-L, L] = [-1, 1]\). The results are shown in Fig. 1(i)-(iii), where the shaded areas indicate the exterior of \(D_w\). Several large and small neutral modes are found, respectively, as indicated by the open and filled circle symbols in Fig. 1. We have confirmed that unstable modes indeed exist between these points along the black solid lines. The flows (i)-(iii) are respectively unstable to the Kelvin-Helmholtz (KH), Taylor (T) and Holmboe (H) instabilities as indicated in Fig. 1. For the case (i), the stratification induces three more unstable modes in addition to the KH instability that originally exists in the mixing layer. As exemplified by these modes as well as the Taylor instability (ii), increasing the stratification (or \(N_B^2\)) generally tends to spawn more unstable modes, whose eigenfunctions are more oscillatory (i.e., \(\lambda_{L\pm}^{(n)}\) and \(\lambda_{R\pm}^{(n)}\) with
Figure 1: Numerically calculated $\lambda_{L}^{(n)}$ and $\lambda_{R}^{(n)}$, $n = 1, 2, \ldots$, as functions of $x_c \in D_w$ for the examples of unstable flows (i)-(iii).
larger \( n \) show up on the positive side). At the same time, however, the width of \( D_w \) tends to be narrowed by increasing \( N_B^2 \), which in turn contributes to stabilization. In the case (iii), \( D_w \) is divided into two parts by the sharply peaked profile of \( N_B^2 \) (or density jump) and the KH mode is split into the Holmboe modes. Here, it should be noted that the unstable modes may exist outside \( D_w \), while the neutral modes are forced to exist inside \( D_w \).

3. Sufficient Conditions for Stability

Now, we recall that Howard [5] has obtained the upper bound of \( \text{Im} C \) as 
\[
\text{Im} C < k^{-1} \max_{[-L,L]} \sqrt{U''^2/4 - N_B^2},
\]
which implies \( \text{Im} C \to 0 \) as \( k \to \infty \). On the other hand, we have shown the absence of neutral modes for sufficiently large wavenumber \( k \) satisfying either \( k^2 > \lambda_{L-}^{(1)} \) or \( k^2 > \lambda_{R-}^{(1)} \) for all \( x_c \) in \( D_w \). Therefore, no unstable mode can exist for such large \( k \). Since the largest eigenvalues, \( \lambda_{L-}^{(1)} \) and \( \lambda_{R-}^{(1)} \), of the Sturm-Liouville problem are easily calculated by the variational method, we can derive a stability condition in the following form.

**Criterion 1.** The flow (2) is spectrally stable for the wavenumber \( k \) that satisfies either

\[
k^2 > - \min_{\psi(-L)=0} \frac{\int_{-L}^{x_c} |P(\psi'^2 + Q\psi^2)dx}{\int_{-L}^{x_c} |P|\psi^2dx}, \tag{11}
\]

or 
\[
k^2 > - \min_{\psi(L)=0} \frac{\int_{x_c}^{L} |P(\psi'^2 + Q\psi^2)dx}{\int_{x_c}^{L} |P|\psi^2dx}, \tag{12}
\]

for all \( x_c \in D_w \).

Obviously, the flow is spectrally stable for all \( k \) if the right hand sides of (11) and (12) are negative for all \( x_c \in D_{w1} \) and for all \( x_c \in D_{w2} \), respectively, and \( D_w = D_{w1} \cup D_{w2} \) (namely, \( \lambda_{L-}^{(1)} \) and \( \lambda_{R-}^{(1)} \) are negative on \( D_{w1} \) and \( D_{w2} \), respectively). Note that either \( D_{w1} \) or \( D_{w2} \) may be the null set and then (11) or (12) will be not applicable.
If $Q(x, x_c) \geq 0$ both on $[-L, x_c]$ for all $x_c \in D_{w1}$ and on $[x_c, L]$ for all $x_c \in D_{w2}$, Criterion 1 immediately proves stability. This observation enables us to derive further stability conditions as follows.

Let $a \in [-L, L]$ be the rightmost point in $D_{w1}$, i.e., $a = \max D_{w1}$. By using the inequality

$$\frac{J_R(x_c) - J_R(x)}{U(x_c) - U(x)} \geq \min_{[-L,a]} \frac{J'_R}{U'}$$

for $x \leq x_c \leq a$, (13)

we get

$$Q(x, x_c) \geq U'^2 \left[ \left( -\frac{1}{2} + \nu_c \right) \frac{U''}{U'^2} + \min_{[-L,a]} \frac{J'_R}{U'} \right], \quad (14)$$
on $[-L, x_c] \subset [-L, a]$. The requirement $Q(x, x_c) \geq 0$ on $[-L, x_c]$ for all $x_c \in D_{w1}$ (for which $0 \leq \nu_c < 1/2$) leads to (15) below. The similar inequality can be also derived for $[x_c, L] \subset [b, L]$ in terms of the leftmost point $b$ in $D_{w2}$. Thus, we obtain the following stability criterion:

**Criterion 2.** The flow (2) is spectrally stable if there exist $a, b \in [-L, L]$ such that

$$\max_{[b, L]} \left( \frac{U''}{U'^2} \right) \leq \min_{[-L,a]} \left( \frac{J'_R}{U'} \right), \quad (15)$$

and

$$\min_{[-L,a]} \left( \frac{U''}{U'^2} \right) \geq \max_{[b, L]} \left( \frac{J'_R}{U'} \right), \quad (16)$$

and $D_w \subset [-L, a] \cup [b, L]$ hold, where (15) or (16) may be omitted when $a = -L$ or $b = L$, respectively.

We remark that, in (15), for example, we should adopt $\sigma = 1/2$ if $\max_{[-L,a]} U'' < 0$, or $\sigma = 1$ otherwise.

From Criterion 2, it is straightforward to obtain the next criterion:

**Criterion 3.** The flow (2) is spectrally stable if there exist $a, b \in [-L, L]$ such that

$$U'' \leq 0 \text{ and } J'_R \geq 0 \text{ on } [-L, a], \quad (17)$$

and

$$U'' \geq 0 \text{ and } J'_R \leq 0 \text{ on } [b, L], \quad (18)$$
and $D_w \subset [-L, a] \cup [b, L]$ hold, where \[17\] or \[18\] may be omitted when $a = -L$ or $b = L$, respectively.

Recall that unstratified shear flows with no inflection point ($U'' \neq 0$) were shown to be stable by Rayleigh [11], and even when a monotonic shear flow ($U' > 0$) has one inflection point $U''(x_I) = 0$, it is still stable if $U'' < 0$ on $[-L, x_I]$ and $U'' > 0$ on $[x_I, L]$ according to Fjørtoft [12]. Criterion 3 asserts that these flows remain stable even with the effect of stratification, if the additional condition on the sign of $J'_R$ is satisfied (where $a = b = x_I$ is chosen for the Fjørtoft case).

Since $J'_R \leq 0$ is equivalent to $(N_B^2)'/N_B^2 = \rho''/\rho' \leq U''/U'$ by definition, the case of $N_B^2 \equiv \text{const.}$ (or $\rho'' \equiv 0$) automatically satisfies the condition on $J'_R$ of Criterion 3. On the contrary, if $J_R$ takes a minimum value in the middle of $[-L, L]$ and it is below $1/4$, Criterion 3 is violated and such a stratification can destabilize an otherwise stable shear flow, like the Taylor instability of Fig. 1(ii).

Criterion 3 is also violated by a $U'$ that has a local maximum in the middle of $D_w$ (i.e., a local maximum of vorticity), which can cause KH instability like the example of Fig. 1(i).

The more detailed Criterion 2 tells us that this destabilization effect of $U''$ (or $J'_R$) may be suppressed by the stabilization effect of $J'_R$ (or $U''$). For example, the flows,

(iv) $U = \arctan(x/2) + x$, $J_R = (1 - 3x/4)/5$,
(v) $U = (x + 3/2)^2$, $J_R = (x^2 + 2)/10$,

on $[-L, L] = [-1, 1]$ are found to be stable by Criterion 2. For the case (iv), the sign of $U''$ violates the Rayleigh-Fjørtoft criterion and $U'$ has a maximum in $D_w$, but the stratification $J_R$ contributes to stabilization so that the inequality \[16\] with $D_w = [b, L]$ holds, as shown in Fig. 2. Conversely, for the case (v), $J_R$ has a minimum that is below $1/4$, but $U'' > 0$ is large enough to satisfy \[16\] with $D_w \subset [b, L]$. 9

4. Concluding Remarks

In summary, by using the method developed in this letter, we can efficiently find singular neutral modes that are embedded in the continuous spectrum. The unstable ranges of wavenumber are searched for by solving the regular Sturm-Liouville problems (7)-(10) for each \( x_c \in D_w \), which requires less labor than solving the TG equation (i.e., a non-self-adjoint eigenvalue problem) for each \( k > 0 \) directly. With the help of numerical computation, this method will be useful for determining stability boundaries for various flows and understanding their instability mechanisms. Based on this method, we have derived new stability criteria (Criteria 1, 2, and 3) as extensions of the Rayleigh-Fjørtoft criterion to stratified flows, which are of course improvements of the Howard-Miles criterion since the local Richardson number is allowed to be less than 1/4 (see Fig. 3).

We expect that the present approach could yields stability boundaries of non-monotonic shear flows and locally unstratified (or constant) densities with additional or different treatments for the singularity. A few specific examples were investigated in earlier works [15, 7, 8], which in particular suggests that the singularity at the critical layer should be replaced by that of Rayleigh’s equation.
when $N_B^2(x_c) = 0$. By making use of the abundant knowledge about Rayleigh’s equa-
tion [10], more detailed stability criteria tailored for these applications will
be discussed elsewhere.
