A B S T R A C T

As the central organ of stress and adaptation to stressors, the brain plays a pivotal role in behavioral and physiological responses that may lead to successful adaptation or to pathophysiology and mental and physical disease. In this context, resilience can be defined as “achieving a positive outcome in the face of adversity”. Underlying this deceptively simple statement are several questions; first, to what extent is this ability limited to those environments that have shaped the individual or can it be more flexible; second, when in the life course does the brain develop capacity for flexibility for adapting positively to new challenges; and third, can such flexibility be instated in individuals where early life experiences have limited that capacity? Brain architecture continues to show plasticity throughout adult life and studies of gene expression and epigenetic regulation reveal a dynamic and ever-changing brain. The goal is to recognize those biological changes that underlie flexible adaptability, and to recognize gene pathways, epigenetic factors and structural changes that indicate lack of resilience leading to negative outcomes, particularly when the individual is challenged by new circumstances. Early life experiences determine individual differences in such capabilities via epigenetic pathways and laying down of brain architecture that determine the later capacity for flexible adaptation or the lack thereof. Reactivation of such plasticity in individuals lacking such resilience is a new challenge for research and practical application. Finally, sex differences in the plasticity of the brain are often overlooked and must be more fully investigated.

1. Introduction

The brain is the central organ of stress and adaptation to stressors because it perceives what is potentially threatening and determines the behavioral and physiological responses (McEwen, 1998; McEwen and Gianaros, 2011). Moreover, the brain is a target of stress and stressful experiences change its architecture, gene expression and function through internal neurobiological mechanisms in which circulating hormones play a role (Gray et al., 2013; McEwen, 2007). In healthy young adult animals, neuroanatomical changes in response to repeated stress are largely reversible (Conrad et al., 1999; Radley et al., 2005), or so it appears, based upon the restoration of dendritic length and branching and spine density. Yet there are underlying changes that can be seen at the level of gene expression and epigenetic regulation which indicate that the brain is continually changing (Gray et al., 2013; Hunter et al., 2013; McEwen, 2007; Nasca et al., 2013). Insofar as brain architecture and associated behavioral states are restored after stressful experiences in ways that appear to be healthy and functional, does this constitute “resilience”? This review examines this question in relation to new insights from the growing topic of epigenetics and gene expression by focusing on recent work on the hippocampus, amygdala and prefrontal cortex after acute and chronic stress and treatment with antidepressant agents.

2. Definitions of resilience

Resilience means to most people “achieving a positive outcome in the face of adversity”. This can involve “bending and not breaking,” that is, recovering from a bad experience. Or it can involve an “active resistance” to adversity through coping mechanisms that operate at the time of trauma (Karatsoreos and McEwen, 2011). But this adaptation does not, by itself, indicate flexibility in successful adaptation to new challenges over the life course. The individual traits that allow the more flexible outcomes undoubt-edly depend upon a foundational capacity of that individual that is...
built upon experiences in the life course, particularly early in life, that promote the development of healthy brain architecture supporting cognitive flexibility that allows the brain to continue to change with ongoing experiences. A healthy brain architecture provides the basis for good self-esteem, and a locus of control for the physiological responses to stressors that are regulated by the central and peripheral nervous systems. We shall now review how the brain and body adapt to challenges, often called “stressors”.

3. How do the brain and body adapt?

3.1. Allostasis, allostatic load and health-related behaviors

The active process of responding to challenges to, and adaptive changes by, an individual is called “allostasis”. This involves multiple mediators (autonomic, cortisol, immune/inflammatory, metabolic, neuromodulators within the brain) that interact non-linearly with each other and promote adaptation in the short run as long as they are turned on efficiently when needed and turned off promptly when no longer needed. Over-use (too much stress) or dysregulation among the mediators (e.g., too much or little cortisol; too much or little inflammatory cytokines) results in cumulative change that is referred to as “allostatic load and overload” (McEwen, 1998).

As the key organ of stress and adaptation, the brain directs “health-related behaviors” (caloric intake, alcohol, smoking, sleep, exercise) that contribute to or ameliorate physiological dysregulation and thereby play a key role in exacerbating or counteracting allostatic load/overload (McEwen, 2007). Brain development and healthy or unhealthy neural function determines in part whether the response to challenges or “stressors” is efficient or dysregulated. The development of self esteem and locus of control and good self regulatory behaviors are key factors that determine whether a challenge, such as going to a new place or giving a speech, will result in “positive stress”, with a satisfying outcome, or have negative consequences. Tolerable stress refers to experiencing stressful major life events that will result in successful coping with minimal allostatic load due to good internal resources and external support. Toxic stress refers to the situation where there is unsuccessful coping due to lack of adequate internal capacities as well as poor external support that may also be based upon inadequate neural architecture to handle the stressors, and “allostatic overload” applies to those toxic stress situations where physiological dysregulation is likely to accelerate development of disease (McEwen and Wingfield, 2003).

3.2. Brain architecture responds to stressors

In the healthy brain, structural remodeling occurs after both acute and chronic stress. The discovery of receptors for glucocorticoids in the hippocampus has led to many investigations in animal models and translation to the human brain using modern imaging methods. The most striking findings from animal models have identified structural plasticity in the hippocampus, consisting of ongoing neurogenesis in the dentate gyrus (Cameron and Gould, 1996) and remodeling of dendrites and synapses in the major neurons of Ammon’s horn (McEwen, 1999). Indeed, neurogenesis in the adult mammalian brain was initially described (Altman and Das, 1965; Kaplan and Bell, 1983) and then suppressed (Kaplan, 2001), only to be rediscovered in the dentate gyrus of the hippocampus (Cameron and Gould, 1994; Gould and McEwen, 1993) in the context of studies of neuron cell death and actions of adrenal steroids and excitatory amino acids in relation to stress. This was further developed to call attention to the generality of neurogenesis across vertebrates (Alvarez-Buylla and Lois, 1995), with recent evidence making it clear that the human hippocampus shows significant neurogenesis in adult life (Spalding et al., 2013). See also Box 1.

The mediators of brain structural plasticity include excitatory amino acids and glucocorticoids, along with a growing list of other mediators such as oxytocin, corticotropin releasing factor, brain derived neurotrophic factor (BDNF), lipocalin-2 and tissue plasminogen activator (tPA) (McEwen, 2010). Moreover, glucocorticoid actions involve both genomic and non-genomic mechanisms that implicate mineralocorticoid, as well as glucocorticoid receptors and their translocation to mitochondria as well as cell nuclei; and, an as-yet unidentified G-protein coupled membrane receptor related to endocannabinoid production (Du et al., 2009; Hill and McEwen, 2010; Popoli et al., 2012).

Box 1

Relevance to neural architecture of the human brain

Studies of the human hippocampus have demonstrated shrinkage of the hippocampus not only in mild cognitive impairment and Alzheimer’s disease (de Leon et al., 1997), but also in Type 2 diabetes (Gold et al., 2007), prolonged major depression (Sheline, 2003), Cushing’s disease (Starkman et al., 1999) and post-traumatic stress disorder (PTSD) (Gurvits et al., 1996). Moreover, in non-disease conditions, such as chronic stress (Gianaros et al., 2007b), chronic inflammation (Marland et al., 2008), lack of physical activity (Erickson et al., 2009) and jet lag (Cho, 2001), smaller hippocampal or temporal lobe volumes have been reported.

So far there is no indication as to whether these changes are due to volume reduction in dentate gyrus due to inhibited neuronal replacement or to dendritic shrinkage or glial cell loss, or a combination of all three. Autopsy studies on depression-suicide have indicated loss of glial cells and smaller neuron soma size (Stockmeier et al., 2004), which is indicative of a smaller dendritic tree.

With regard to Type 2 diabetes, it should be emphasized that the hippocampus has receptors for, and the ability to take up and respond to insulin, ghrelin, insulin-like growth factor-1 (IGF1) and leptin; and that IGF-1 mediates exercise-induced neurogenesis (McEwen, 2007). Thus, besides its response to glucocorticoids, the hippocampus is an important target of metabolic hormones that have a variety of adaptive actions in the healthy brain which is perturbed in metabolic disorders, such as diabetes (McEwen, 2007).

The implications of stress and glucocorticoid effects in the hippocampus have led to exploration of other brain regions involved in cognition, mood and behavioral self-regulation. The amygdala shows quite different responses to acute and chronic stress compared to the hippocampus. The amygdala responds to glucocorticoids in the formation of emotionally-charged memories (Roozendaal et al., 2004), and acute stress causes a delayed formation of dendritic spines in basolateral amygdala neurons and an increase of anxiety after 10 days (Mitra et al., 2005). Chronic stress of the same type that impairs dentate gyrus neurogenesis and cause dendritic shrinkage and spine loss in Ammon’s horn neurons, causes expansion of dendrites in the basolateral amygdala (Vyas et al., 2002) while causing spine down-regulation in the medial amygdala (Bennur et al., 2007). The latter is dependent on tissue plasminogen activator (tPA) while the former does not (Bennur et al., 2007). See Box 2.

The implications of stress and glucocorticoid effects in the hippocampus have led to exploration of other brain regions involved in cognition, mood and behavioral self-regulation. The amygdala shows quite different responses to acute and chronic stress compared to the hippocampus. The amygdala responds to glucocorticoids in the formation of emotionally-charged memories (Roozendaal et al., 2004), and acute stress causes a delayed formation of dendritic spines in basolateral amygdala neurons and an increase of anxiety after 10 days (Mitra et al., 2005). Chronic stress of the same type that impairs dentate gyrus neurogenesis and cause dendritic shrinkage and spine loss in Ammon’s horn neurons, causes expansion of dendrites in the basolateral amygdala (Vyas et al., 2002) while causing spine down-regulation in the medial amygdala (Bennur et al., 2007). The latter is dependent on tissue plasminogen activator (tPA) while the former does not (Bennur et al., 2007). See Box 2.
The prefrontal cortex (PFC) is another, now well-studied, target of chronic stress (McEwen and Morrison, 2013). In the same chronic stress models that lead to amygdala neuronal hypertrophy and shrinkage of dendrites in hippocampus, there is shrinkage of dendrites and loss of spines throughout the medial prefrontal cortex while dendrites expand in the orbitofrontal cortex (OFC) (Liston et al., 2006). Because the OFC is involved in determining the salience of reward or punishment (Schoenbaum and Roesch, 2005), this may reinforce the changes in the basolateral amygdala. For the medial prefrontal cortex, stress-induced impairment has been linked to poor cognitive flexibility in both animal and human studies (Dias-Ferreira et al., 2009; Liston et al., 2009, 2006). Moreover, circadian disruption impairs cognitive flexibility and causes shrinkage of medial prefrontal cortical dendrites (Karatsoreos et al., 2011). The mechanism for medial PFC dendritic remodeling is likely to involve the same mechanisms as those in the hippocampus, namely, excitatory amino acids and glucocorticoids (Cerqueira et al., 2005; Martin and Wellman, 2011).

The structural changes are largely reversible in healthy young animals after the termination of stress. See Box 3. When the stress is over, remodeled brain circuits recover at least in younger animals with healthy brain architecture (Bloss et al., 2010; Radley et al., 2005), but there are clues that the recovered state is not the same as the initial state. For example, in the studies of recovery from chronic stress in the medial prefrontal cortex of young adult rats, the retraction of apical dendrites during chronic stress was from distal dendrites and the re-growth of those dendrites during recovery was from the more proximal dendrites (Fig. 1) (Goldwater et al., 2009). Yet there was reversal of deficits in D1 receptor expression and recovered function in terms of dopamine enhanced LTP during recovery from chronic stress, and it is not yet clear if the differences in dendritic retraction and regrowth reflect any reorganization of neuroanatomical circuitry (Goldwater et al., 2009). This apparent reversibility hides the fact that genomic responses to stressors are dependent on the stress-history of the individual, as will be elaborated below. Moreover, there is clearly loss of reversibility in aging (Bloss et al., 2010) and also a failure to show plasticity in response to stress as a result of maternal separation stress in infancy (Eiland and McEwen, 2012) and haploinsufficiency (Magarinos et al., 2011) or overexpression (Govindarajan et al., 2006) of brain derived neurotrophic factor (BDNF).

4. Sex differences and what this means for the rest of the brain

All of the animal model studies of stress effects summarized above and below were carried out on male rodents. Thus, it is very important to note before proceeding further by discussing sex differences in how the brain responds to stressors. Indeed, female rodents do not show the same pattern of neural remodeling after chronic stress as do males. The first realization of this was for the hippocampus, in which the remodeling of CA3 dendrites did not occur in females after CRS, even though all the measures of stress hormones indicated that the females were experiencing the stress as much as males (Galea et al., 1997). Females and males also differ in the cognitive consequences of repeated stress, with males showing impairment of hippocampal dependent memory, whereas females do not (Bowman et al., 2001; Luine et al., 1994, 2007).

In contrast, acute tail shock stress during classical eyelid blink conditioning improves performance in males, but suppresses it in females (Wood and Shors, 1998) by mechanisms influenced by gonadal hormones in development and in adult life (Shors and Miesegaes, 2002; Wood et al., 2001). However, giving male and female rats control over the shock abolishes both the stress effects and the sex differences (Leuner et al., 2004). These findings suggest...
sex differences has undergone a revolution and much more is to come (Cahill, 2006; Laje et al., 2007; McEwen, 2009; McEwen and Lasley, 2005; Meites, 1992), including insights into X and Y chromosome contributions to brain sex differences (Carruth et al., 2002). In men and women, neural activation patterns to the same tasks are quite different between the sexes even when performance is similar (Derntl et al., 2010). This leads to the concept that men and women often use different strategies to approach and deal with issues in their daily lives, in part because of the subtle differences in brain architecture. Nevertheless, from the standpoint of gene expression and epigenetic effects, the principles of what we have learned in animal models regarding plasticity, damage and resilience are likely to apply to both males and females.

5. Lessons from gene expression

We have noted that resilience means to most people achieving a positive outcome in the face of adversity. Even when the healthy brain and associated behavior appears to have recovered from a stressful challenge, studies of gene expression have revealed that the brain is not the same, just as the morphology after recovery appears to be somewhat different from what it was before stress (Goldwater et al., 2009). See Fig. 1. Transcriptional profiling of the mouse hippocampus has revealed that after a recovery period from chronic stress, which is equivalent to the duration of the stressor (21d) and is sufficient to restore anxiety-like behaviors to pre-stress baselines, the expression levels of numerous genes remained distinct from the stress naive controls (Gray et al., 2013). See Fig. 2. Further, exposure to a novel swim stress 24 h after chronic stress or after a 21d recovery period from the chronic stress, produced distinct gene expression profiles from mice that experienced a swim stress but had no history of chronic stress. Together, these findings suggest that gene expression patterns after recovery from stress do not reflect a return to the stress naive baseline (even when the behaviors have recovered) and chronic stress alters reactivity to future stressors. Studies examining longer recovery periods, as well as how intermittent stress during recovery might alter gene expression will be necessary to answer whether these seemingly lasting changes might eventually reverse or if additional stressors can compound certain changes. These changes in transcriptome reactivity represent one molecular signature for resilience that are themselves likely to be driven by epigenetic changes discussed in the next section.

Importantly, recent evidence has suggested that the in vivo transcriptional changes in response to stress represent a synthesis of multiple cellular pathways, not simply CORT activation of GR-dependent transcription. Chronic stress increases inflammatory tone and this release of cytokines can activate other signaling pathways, such as NF-kB-dependent transcription. Microarray studies have found that glucocorticoid injections produce distinct gene expression profiles from naive acute stress (Fig. 2B) and that the gene expression response to a glucocorticoid injection changes after exposure to chronic stress (Datson et al., 2013; Gray et al., 2013). In support of these findings, in vitro studies have demonstrated that simultaneous activation of GR and NF-kB-dependent transcription results in a unique pattern of gene expression that is distinct from the predicted sum of either pathway activated alone (Rao et al., 2011). These findings illustrate that gene expression changes in response to stress are not solely the product of glucocorticoid activity. Increasingly, research into stress resilience is looking beyond GR-dependent transcription in order to capture the complexity of the cellular response to stress.

6. Lessons from epigenetic influences

Functional insights into the ever-changing brain come from studies of epigenetic regulation. The term “epigenetics” now
extends beyond its original definition (Waddington, 1942) to include the continuous, seamless interaction between genes and the factors which regulate gene expression over the life course. The core of the genomic response to those environmental factors such as hormones, cytokines and chemokines and other neuro-modulators involves modification of histones (Maze et al., 2013), methylation of cytosine residues on DNA, non-coding RNA’s that modify expression of mRNA molecules, and retrotransposon DNA elements (Mehler, 2008).

In our studies of stress neurobiology, acute restraint stress was shown to increase expression in the dentate gyrus of a repressive histone mark, H3K9me3, and this was accompanied by the repression of certain retrotransposon elements of as yet unidentified function; this repressive response habituates with repeated stress raising the possibility of increased genomic instability. Such instability may manifest itself in terms of genomic activity that is no longer responsive to environmental influences or lead to genomic activity that is increased as a result of chronic stress, as in accelerated aging (Hunter et al., 2013, 2012). Loss of reversal of stress induced structural plasticity, as seen in aging rats (Bloss et al., 2010) is one example; and increased expression of inflammatory mediators together with loss of cholinergic and dopaminergic function (Bloss et al., 2008) is another.

In contrast, there are examples of epigenetic activation of neural activity. Indeed, acute swim stress as well as novelty exposure induce an activational histone mark in dentate gyrus, namely, acetylation of lysine residue 14 and phosphorylation of the serine residue on histone H3, which is dependent on both GR and NMDA activation and is associated with c-fos induction among other genes (Reul and Chandramohan, 2007). Acetylation of another lysine residue, K27 on histone H3, is associated with increased expression of metabotropic glutamate receptor, mGlu2, in hippocampus of...
Flinders Sensitive Line (FSL) rats as shown by chromatin immunoprecipitation (Nasca et al., 2013). mGlu2 is known to exert an inhibitory tone on glutamate release from synapses. The acetylating agent l-acetylcarnitine (LAC), a naturally occurring substance, behaves as an antidepressant, at least in part by the epigenetic up-regulation of mGlu2 receptors via this epigenetic mechanism. LAC causes a rapid and long-lasting antidepressant effect in both FSL rats and in mice exposed to chronic unpredictable stress, which, respectively, model genetic and environmentally induced depression. Beyond the epigenetic action on the acetylated H3K27 bound to the Grm2 promoter, LAC also increased acetylation of NF-κB-p65 subunit, thereby enhancing the transcription of Grm2 gene encoding for the mglu2 receptor in hippocampus and prefrontal cortex. The involvement of NF-κB in LAC antidepressant-like effects supports a growing literature that shows depression may be associated with a chronic inflammatory response (Dantzer et al., 2008).

Importantly, LAC reduced the immobility time in the forced swim test and increased sucrose preference as early as 3 d of treatment, whereas 14 d of treatment were needed for the antidepressant effect of chlorimipramine (Nasca et al., 2013). This suggests LAC is important for stress resilience.

A recent study from our laboratory has shown that hippocampal expression of mglu2, is also a marker of individual susceptibility to mood disorders. Interestingly, mglu2 is the same receptor regulating inhibitory glutamate tone that has been shown to be elevated by treatment with LAC in FSL rats to reverse depressive-like behavior (Nasca et al., 2013). Using a novel and acute approach for rapidly screening an inbred population of laboratory animals, it has been shown that both chronic unpredictable stress and acute restraint stress results in individual behavioral and molecular differences in wild-type mice that are more (HS) or less (LS) susceptible to stress-induced mood abnormalities. At the molecular level, HS and LS mice differ in the ability of stress to induce a decrease of mglu2 receptor expression in hippocampus. Mapping the steps of this intricate dance that allow some individuals to face adverse life experience, the HS subset of mice was associated with higher baseline levels of MR genes than the LS subset, showing an MR-dependent down-regulation of mglu2 receptors in hippocampus. These findings led to the introduction of the epigenetic allostasis model, which incorporates an epigenetic core into the allostasis—allostatic load model of stress and adaptation to emphasize the gene—environment interactions. In particular, the epigenetic allostasis model suggests that a non-shared experience early in life may epigenetically set each individual, via expression of MR genes, to a somewhat different trajectory of development as far as responses to subsequent stressful life experiences (Nasca et al., September 2014). In agreement, juvenile stress was associated with increased hippocampal MR mRNA levels and anxiety-like behavior in adulthood (Brydges et al., 2014). See Fig. 3.

7. The life course and the epigenetics of individual differences

The individual traits that allow these adaptive or maladaptive outcomes depend upon the unique neurological capacity of each
DNA rediverge over the life course in patterns of CpG methylation of their to those differences begin early in life. For example, identical twins neurogenesis rates (Freund et al., 2013) and the in cortex (Miller et al., 2012) to differences in MR levels in hippo-
many ways ranging from length of dendrites in the prefrontal 
new challenges. Genetically similar or identical individuals differ in either promotes or fails to promote gene expression responses to or unhealthy brain architecture and in epigenetic regulation that be noted below. See Box 4. Animal models have contributed enormously to our understanding of how the brain and body are affected, starting with the “neonatal handling” studies of Levine and Denenberg (Levine et al., 1967) and the recent, elegant work of Meaney, Szyf and colleagues involving methylation of CpG residues in DNA (Meaney and Szyf, 2005). Such epigenetic, transgenerational effects transmitted by maternal care are central to these findings. Besides the amount of maternal care, the consistency over time of that care and the exposure to novelty are also very important not only in rodents (Akers et al., 2008; Tang et al., 2000), but also in monkey models (Parker et al., 2006). Prenatal stress impairs hippocampal development in rats, as does stress in adolescence (Isgor et al., 2004). Insufficient maternal care in ro-
dents (e.g., (Rice et al., 2008)) and the surprising attachment shown by infant rats to their less-attentive mothers appears to involve an immature amygdala (Moriceau and Sullivan, 2006), activation of which by glucocorticoids causes an aversive conditioning response to emerge. Maternal anxiety in the variable foraging demand (VFD) model in rhesus monkeys leads to chronic anxiety in the offspring, as well as signs of metabolic syndrome (Coplan et al., 2001; Kaufman et al., 2005).

Box 4
When things go wrong early in life

In studies of adverse childhood experiences (ACE) in human populations (Felitti et al., 1998), there are reports of increased inflammatory tone, not only in children, but also in young adults related to early life abuse, that includes chronic harsh language, as well as physical and sexual abuse (Danese et al., 2008; Miller and Chen, 2010). It should be noted that the ACE study was carried out in a middle class population (Anda et al., 2010), indicating that poverty and low socioeconomic status (SES) are not the only source of early life stressors.

Nevertheless, low SES does increase the likelihood of stressors in the home and neighborhood, including also toxic chemical agents such as lead and air pollution (McEwen and Tucker, 2011), and chaos in the home is associated with development of poor self-regulatory behaviors, as well as obesity (Evans et al., 2008). Moreover, low SES children are found to be more likely to be deficient in language skills, as well as self-regulatory behaviors and also in certain types of memory that are likely to be reflections of impaired development of parasympathetic language centers, prefrontal cortical systems and temporal

lobe memory systems (Farah et al., 2006; Hart and Risley, 1995). Low SES is reported to correlate with smaller hippocampal volumes (Hanson et al., 2011), and lower subjective SES, an important index of objective SES, is associated with reduction in prefrontal cortical gray matter (Gianaros et al., 2007a). Moreover, having grown up in lower SES environment is accompanied by greater amygdala reactivity to angry and sad faces (Gianaros et al., 2008), which, as noted above, may be a predisposing factor for early cardiovascular disease that is known to be more prevalent at lower SES levels (Adler et al., 1993). Finally, depression is often associated with low SES, and children of depressed mothers, followed longitudinally, have shown increased amygdala volume while hippocampal volume was not affected (Lupien et al., 2011).

On the positive side, there are the “reactive alleles.” Genes that in nurturing environments facilitate beneficial outcomes when compared to less reactive alleles, even though those same alleles can enhance adverse outcomes in a stressful early life environment (Boyce and Ellis, 2005; Caspi et al., 2003; Obradovic et al., 2010; Suomi, 2006). Regarding adverse outcomes and good and bad “environments”, it must be recognized that allostatic processes are adjusted via epigenetic influences to optimize the individuals adaptation to, and resulting fitness for, a particular environment, whether more or less threatening or nurturing (Del Giudice et al., 2011). Yet, there are “trade-offs” in terms of physical and mental health that, on the one hand, may increase the likelihood of passing on one’s genes by improving coping with adversity and enhancing mental health and overall reproductive success, but, on the other hand, may impair later health, e.g., by eating of “comfort foods” (see for example (Jackson et al., 2010)).

8. Can we reverse adverse changes?

What can be done to remediate the effects of chronic stress, as well the biological embedding associated with early life adversity? Epigenetics in its original meaning (Waddington, 1942) refers to the emergence at each stage of development of features of the organism not present before or even predictable from the prior state through cellular differentiation. As discussed above, genetic factors interact seamlessly with environmental influences not only during development but also in adult life, leading to the newer meaning of “epigenetics”. Thus at each stage of development there is no “going back” and a new set of possibilities emerges that offer opportunities for epigenetic influences. Interventions will not, therefore, “reverse” developmental events but rather produce compensatory mechanisms (Caldji et al., 1998). Indeed, development never ends and adolescents, young adults, mature and aging individuals continue to show the results of experiences, including opportunities for redirection of unhealthy tendencies through a variety of interventions. One of the most interesting interventions in animal models is the use of an “enriched environment” to reverse effects of early life maternal separation on HPA and behavioral responses (Francis et al., 2002), indicating the potential power in humans of psychosocial interventions after the early life trauma.

Interventions to foster compensatory mechanisms may involve pharmaceutical, as well as behavioral, or “top-down” interventions (i.e., interventions that involve integrated CNS activity). These include cognitive-behavioral therapy, physical activity and programs that promote social support, social integration, and developing meaning and purpose in life (Ganzel and Morris, 2011; McEwen and Gianaros, 2011). More targeted interventions for
emotional and cognitive dysfunction may arise from fundamental studies of such developmental processes as the reversal of amblyopia and other conditions by “releasing the brakes” that retard structural and functional plasticity (Vetencourt et al., 2008). It should be noted that many of these interventions that are intended to promote plasticity and slow decline with age, such as physical activity and positive social interactions that give meaning and purpose, are also useful for promoting “positive health” and “eudaimonia” (Ryff and Singer, 1998; Singer et al., 2005) independently of any notable disorder and within the range of normal behavior and physiology (Ryff, 2014).

Moreover, interventions directed towards changing physiology and brain function may be useful when adaptation to a particular environment has resulted in an individual who then chooses, or is forced to adapt to a different, e.g. more or less threatening or nurturing, environment. A powerful “top down” therapy (i.e., an activity, usually voluntary, involving activation of integrated nervous system activity, as opposed to pharmacologic therapy which has a more limited target) is regular physical activity, which has actions that improve prefrontal and parietal cortex blood flow and enhance executive function (Colcombe et al., 2004). Moreover, regular physical activity, consisting of walking an hour a day, 5 out of 7 days a week, increases hippocampal volume in previously sedentary adults (Erickson et al., 2011). This finding complements work showing that fit individuals have larger hippocampal volumes than sedentary adults of the same age-range (Erickson et al., 2009). It is also well known that regular physical activity is an effective antidepressant and protects against cardiovascular disease, diabetes and dementia (Babyak et al., 2000; Snyder et al., 2010). Moreover, intensive learning has also been shown to increase volume of the human hippocampus (Draganski et al., 2006). Furthermore, the evidence that the novel antidepressant candidate, LAC, exerts fast antidepressant-like effects in a genetic animal model where a LAC deficiency was found in the hippocampus and prefrontal cortex, prompts investigation of how lifestyle as well as diet, vitamin intake or depletion, oxidative stress and the aging process will determine epigenetic states in ways yet unidentified (Denu, 2007; Nasca et al., 2013).

Social integration, social support and finding meaning and purpose in life are known to be protective against allostatic load (Seeman et al., 2002) and dementia (Boyle et al., 2010). Programs such as the Experience Corps, which promotes both cognitive adaptations along with increased physical activity, have been shown to slow the decline of physical and mental health and to improve prefrontal cortical blood flow in a similar manner to regular physical activity (Carlson et al., 2009; Fried et al., 2004).

Depression and anxiety disorders are examples of a loss of resilience, in the sense that changes in brain circuitry and function, caused by the stressors that precipitate the disorder, become “locked” in a particular state and thus need external intervention. Indeed, prolonged depression is associated with shrinkage of the hippocampus (Sheline, 1996, 2003) and prefrontal cortex (Drevets et al., 1997). While there appears to be no neuronal loss, there is evidence for glial cell loss and smaller neuronal cell nuclei (Rajkowska, 2000; Stockmeier et al., 2004), which is consistent with a shrinking of the dendritic tree described above after chronic stress. Indeed, a few studies indicate that pharmacological treatment may reverse the decreased hippocampal volume in unipolar (Vythiltingam et al., 2004) and bipolar (Moore et al., 2000) depression, but the possible influence of concurrent cognitive-behavioral therapy in these studies is unclear.

Depression is more prevalent in individuals who have had adverse early life experiences (Anda et al., 2010). BDNF may be a key feature of the depressive state and elevation of BDNF by diverse treatments ranging from antidepressant drugs to regular physical activity may be a key feature of treatment (Duman and Monteggia, 2006). Yet, there are other potential applications, such as the recently reported ability of fluoxetine to enhance recovery from stroke (Chollet et al., 2011). However, a key aspect of this new view (Castren and Rantamaki, 2010) is that the drug is opening a “window of opportunity” that may be capitalized by a positive behavioral intervention, e.g., behavioral therapy in the case of depression or the intensive physiotherapy to promote neuroplasticity to counteract the effects of a stroke.

This is consistent with animal model work that shows that ocular dominance imbalance from early monocular deprivation can be reversed by patterned light exposure in adulthood that can be facilitated by fluoxetine, on the one hand (Vetencourt et al., 2008) and food restriction, on the other hand (Spoldoro et al., 2011). Investigations of underlying mechanisms for the re-establishment of a new window of plasticity are focusing on the balance between excitatory and inhibitory transmission and removing molecules that put the “brakes” on such plasticity (Bavelier et al., 2010).

It is important to reiterate that successful behavioral therapy, which is tailored to individual needs, can produce volumetric changes in both prefrontal cortex in the case of chronic fatigue (de Lange et al., 2008), and in amygdala, in the case of chronic anxiety (Holzel et al., 2010). This reinforces two important messages: i. that plasticity-facilitating treatments should be given within the framework of a positive behavioral or physical therapy intervention; and ii. that negative experiences during the window may even make matters worse (Castren and Rantamaki, 2010). In that vein, it should be noted that excess BDNF also has the ability to promote pathophysiology, such as seizures in some instances (Heinrich et al., 2011; Kokaia et al., 1995; Scharfman, 1997).

9. Conclusion and future directions

Beyond recognizing resilience as “achieving a positive outcome in the face of adversity”, the flexibility of the brain based upon healthy architecture emerges as a primary consideration. We have seen that brain architecture continues to show plasticity throughout adult life and studies of gene expression and epigenetic regulation reveal a dynamic and ever-changing brain. Ongoing work is identifying those biological changes that underlie flexible adaptability, as well as recognizing gene pathways, epigenetic factors and structural changes that indicate lack of resilience and which may lead to negative outcomes, particularly when the individual is challenged by new circumstances. We have seen that early life experiences determine individual differences in such capabilities via epigenetic pathways and the laying down of brain healthy architecture emerges as a primary consideration. We have seen that brain architecture continues to show plasticity throughout adult life and studies of gene expression and epigenetic regulation reveal a dynamic and ever-changing brain. Ongoing work is identifying those biological changes that underlie flexible adaptability, as well as recognizing gene pathways, epigenetic factors and structural changes that indicate lack of resilience and which may lead to negative outcomes, particularly when the individual is challenged by new circumstances. We have seen that early life experiences determine individual differences in such capabilities via epigenetic pathways and the laying down of brain architecture that determines the future capacity for flexible adaptation or the lack thereof. Reactivation of such plasticity in individuals lacking such resilience is a new challenge for research and practical application and top-down interventions such as physical activity, social support, behavioral therapies including mindfulness and mediation and finding meaning and purpose are emerging as important new directions where pharmaceutical agents will not by themselves be effective but may be useful in combination with the more holistic interventions. And, finally and most importantly, even though the principles of epigenetic neurobiology apply to both genders, determining how the processes involved in resilience differ between men and women constitutes an important challenge for future research and practical application.
