Abstract
We show that forward mode automatic differentiation and symbolic differentiation are equivalent in the sense that they both perform the same operations when computing derivatives. This is in stark contrast to the common claim that they are substantially different. The difference is often illustrated by claiming that symbolic differentiation suffers from “expression swell” whereas automatic differentiation does not. Here, we show that this statement is not true. “Expression swell” refers to the phenomenon of a much larger representation of the derivative as opposed to the representation of the original function.

Common Myths
When distinguishing automatic differentiation from symbolic differentiation one frequently encounters the following myths:

1. Symbolic differentiation leads to “expression swell”, i.e., careless symbolic differentiation can easily produce exponentially large symbolic expressions. Hence, automatic differentiation is more efficient than symbolic differentiation.

2. Symbolic and automatic differentiation are very different, especially in the presence of control flow statements like if or while loops.

3. Symbolic differentiation faces the problem of converting a computer program into a single expression.

4. After computing a derivative using symbolic differentiation, which might lead to an exponential growth, one can reduce the size of the resulting expressions by using common subexpressions. However, this is has to be done very carefully and is not straightforward and the intermediate representation will still see an exponential growth.

The purpose of this paper is to shed some light onto these issues and show, that they are not true. In fact, we will show that forward mode automatic differentiation and symbolic differentiation are equivalent.

1 Introduction
Computing derivatives is a fundamental task in computer science, especially in optimization and machine learning. Most optimization schemes rely on derivative information when minimizing a function. However, computing derivatives by hand is error prone and can be a time consuming task, especially when the function to be differentiated is more complex. Hence, methods for automatically computing derivatives have been designed. The two major approaches that can be found in the literature are automatic differentiation and symbolic differentiation. Symbolic differentiation is basically
what one knows from high school. Automatic differentiation refers to the fact, that one can compute
derivatives even for computer programs that compute functions. Automatic differentiation is often
also referred to as algorithmic differentiation. The literature and tools on automatic differentiation is
extensive, see, e.g., [2, 4, 5, 6, 8, 9, 10, 11]. Its popularity increased significantly over the last few
years, especially in the area of machine learning/deep learning [11, 12, 13, 14, 17, 18, 19] where it
is necessary to compute gradients of loss functions of deep nets.

It is often claimed in the literature that automatic differentiation is \textit{not} symbolic differentiation. To
tell them apart, the phenomenon of “expression swell” is used [10] page 3. However, the difference is
not really explained and stays in the dark. On the other hand it is sometimes hard to put one tool into
its right category, i.e., either automatic differentiation or symbolic differentiation. For instance, the
Theano framework [16] that has been widely used in the machine learning community is sometimes
said to use automatic differentiation and sometimes said to use symbolic differentiation [3]. Here,
we explain why it is hard to tell both approaches apart by showing that they are in fact equivalent.
They both perform the same operations when computing derivatives. The only difference they
have is the underlying data structure. Automatic differentiation operates on directed acyclic graphs
(DAGs) whereas symbolic differentiation operates on expression trees or expression forests if one
allows common subexpressions. However, when we allow common subexpressions in symbolic
differentiation, then forward mode automatic differentiation and symbolic differentiation compute
the same result. We will also show that the phenomenon of “expression swell” does \textit{not} originate
from the differentiation process but from transforming a DAG into a tree when disallowing common
subexpressions.

2 Expression Representation

By expressions we understand mathematical expressions like $\sin(x_1 + x_2) \cos(x_1 + x_2)$. They can be
represented by expression DAGs (also known as computational graphs or execution trace), expression
trees, or expression forests with common subexpressions. Figure 1 illustrates the difference for the
function $f(x_1, x_2) = \sin(x_1 + x_2) \cos(x_1 + x_2)$. Obviously, an expression tree is also an expression
DAG. On the other hand, an expression DAG can be converted into a tree simply by unfolding. The
execution of a computer program results in an expression DAG. For instance, the following Python
code results in the above expression DAG.

```python
def f(x1, x2):
    t1 = x1 + x2
    f = sin(t1) * cos(t1)
    return f
```

When unfolding an expression DAG into an expression tree without common subexpressions it can
become exponentially large. An example is given in Figure 2. However, when allowing common
Figure 2: Expression DAG (left), expression tree (middle), and expression forest (right) showing the phenomenon of “expression swell” and the use of common subexpressions to prevent it.

Subexpressions it can be converted one-to-one where the resulting forest has the same size as the DAG. The following Python code corresponds to this example.

```python
def f(x1):
    t1 = x1 * x1
    t2 = t1 * t1
    f = t2 * t2
    return f
```

Now, we see an expression swell when converting a DAG into a tree. However, this is totally independent of computing derivatives. When allowing common subexpressions, we do not see an expression swell. This expression swell is often put forward as an argument for distinguishing between automatic and symbolic differentiation. Here, we see that it is not connected to computing derivatives. Rather, it is a matter of the expression representation. Note, that when allowing common subexpressions such an expression swell does not occur.

3 Equivalence of Forward Mode Automatic Differentiation and Symbolic Differentiation

In this section we will first review forward mode automatic differentiation and symbolic differentiation, and then we will show their equivalence.

3.1 Forward Mode Automatic Differentiation

Given an expression DAG $D = (V, E)$, forward mode automatic differentiation proceeds as follows when computing the derivative with respect to the input variable $x_j$. Each internal node $v_i$ will eventually store the derivative $\frac{\partial v_i}{\partial x_j}$ that is commonly denoted as $\dot{v}_i$. Forward mode proceeds from input to output nodes. At the nodes representing the input variable $x_i$, the derivative $\frac{\partial v_i}{\partial x_j}$ is stored. Then, the derivatives that are stored at the remaining nodes, here called $v_i$, are iteratively computed by summing over all their incoming edges using the following equation:

$$\dot{v}_i = \frac{\partial v_i}{\partial x_j} = \sum_{v: (v, v_i) \in E} \frac{\partial v_i}{\partial v} \cdot \frac{\partial v}{\partial x_j} = \sum_{v: (v, v_i) \in E} \frac{\partial v_i}{\partial v} \dot{v}_i,$$  

(1)

where the $\dot{v} = \frac{\partial v}{\partial x_j}$ are the partial derivatives that have been computed before and are stored at the nodes $v$. Finally, the derivative of the function $f$ that is represented by the expression DAG is stored at the output node.

3.2 Symbolic Differentiation

Symbolic differentiation applies the following two rules iteratively to a given function in order to compute its derivative.
If the function is unary, e.g., sine, cosine, etc., it applies the following rule
\[
\frac{\partial f(g(x))}{\partial x} = \frac{\partial f}{\partial y} \cdot \frac{\partial g}{\partial x}.
\]  
(2)

In case of binary functions, e.g., addition, multiplication, etc., symbolic differentiation applies
\[
\frac{\partial f(g_1(x), g_2(x))}{\partial x} = \frac{\partial f}{\partial g_1} \cdot \frac{\partial g_1}{\partial x} + \frac{\partial f}{\partial g_2} \cdot \frac{\partial g_2}{\partial x}.
\]  
(3)

All rules from Calculus 101 can be reduced to these two rules. For instance, the multiplication rule is commonly known as \(\frac{\partial (uv)}{\partial x} = u \frac{\partial v}{\partial x} + v \frac{\partial u}{\partial x}\). The following sequence shows that this follows from Equation (3). We have
\[
\frac{\partial (uv)}{\partial x} = u \frac{\partial v}{\partial x} + v \frac{\partial u}{\partial x} = \frac{\partial f}{\partial g_1} \cdot \frac{\partial g_1}{\partial x} + \frac{\partial f}{\partial g_2} \cdot \frac{\partial g_2}{\partial x},
\]

where the binary function \(f(., .)\) is the multiplication operation, \(g_1 = u\), and \(g_2 = v\).

Please note, that the input expression is usually stored in an expression tree or expression forest with common subexpressions. Now there are two important questions that remain to be answered:

**Question 1:** How does symbolic differentiation proceed when encountering common subexpressions?

We illustrate this problem by the following example: Suppose we are differentiating a multiplication node \(f = uv\). The derivative would be \(\frac{\partial f}{\partial x} = u \frac{\partial v}{\partial x} + v \frac{\partial u}{\partial x}\). Note, that \(u\) (and also \(v\)) appear in the original function as well as in the derivative. There are three possibilities to store the result.

1. Copy the whole subtree representing \(u\).
2. Store a pointer to the subtree representing \(u\).
3. Introduce \(u\) as a common subexpression.

All three options are valid possibilities. Option 1 will result in a tree as the output, Option 2 will result in a DAG, and Option 3 in a forest where each tree represents a common subexpression. Conceptually, Option 2 and Option 3 are identical. And this is also how one would implement symbolic differentiation. It is much easier to just store a pointer to the subtree \(u\) instead of copying the whole subtree \(u\). And since common subexpressions are allowed, turning this into a forest with common subexpressions is also trivial.

**Question 2:** Should intermediate results be stored?

Consider for instance the expression \(f = u + u\). Blindly computing the derivative would require to compute the derivative of \(u\) twice. Whenever there is the need for computing the derivative of a subtree \(u\), then one can simply check, if it has been done before. In this case, one does not compute it again but can reuse the old result.

### 3.3 Equivalence

Each internal node in an expression DAG can have either one or two incoming edges. In case a node has one incoming edge, the differentiation Rule (1) for forward mode automatic differentiation is equivalent to the differentiation Rule (2) for symbolic differentiation. In case of two incoming edges, it is equivalent to rule (3) in symbolic differentiation. So obviously, both approaches perform the same operations.

In symbolic differentiation, if one stores only a pointer to common subtrees, or introduces a common subexpression (Option 2 and Option 3 in Question 1) then this is exactly how automatic differentiation proceeds.

Furthermore, if one stores intermediate results and reuses them (Question 2) then symbolic differentiation and forward mode automatic differentiation are identical.
4 Demystifying the Common Myths

It should be obvious now, that the myths that are commonly encountered when talking about automatic and symbolic differentiation are not true. The distinction between them is rather artificial. Especially, the claim of the “expression swell”, i.e., careless symbolic differentiation can easily produce exponentially large expressions is not true. Instead, it will lead to the same result as forward mode automatic differentiation when intermediate results are stored as common subexpressions. This can be done easily. Hence, also the claim that common subexpressions need to be carefully determined after the differentiation process is not true. They can be simply collected during the differentiation process.

When the input is a tree of size $n$, then the resulting tree of the derivative will be of size at most $O(n)$ when storing only pointers to common subtrees and at most $O(n^2)$ when copying every subtree during the symbolic differentiation process. There is no exponential growth here. This misconception can be explained maybe by the following fact. When turning a DAG into a tree, one might see an exponential growth. But this is unrelated to differentiation. And if one turns a DAG into a forest with common subexpression then the size of the output stays the same (Myth 1).

4.1 Speelpenning’s Example

Often, Speelpenning’s example [15] is brought forward to illustrate that symbolic differentiation is inefficient. Speelpenning’s example is the following. Consider the function $f(x_1, x_2, \ldots, x_n) = x_1x_2\ldots x_n$. When computing the gradient with respect to $x = (x_1, x_2, \ldots, x_n)$, symbolic differentiation would output

$$\nabla f = \begin{pmatrix}
    x_2x_3\ldots x_n \\
    x_1x_3\ldots x_n \\
    \vdots \\
    x_1x_2\ldots x_{n-1}
\end{pmatrix}$$

It is argued that the output is unnecessary large and there are quite a number of common subexpressions that now need to be identified. This is not true. What is displayed is the final output. However, this is the final output after the removal of common subexpressions. In between, they have already been computed in the same way as in forward mode automatic differentiation. Hence, symbolic differentiation is as efficient as forward mode automatic differentiation (Myth 4).

Summing up, Speelpenning’s example rather serves as an example why reverse mode automatic differentiation is more efficient in case of many input variables and one output function.

4.2 Control Structures

When using operator overloading in automatic differentiation, control structures are easily circumvented since they do not appear in the computational graph, also known as the execution trace. That is, even when the code contains control structures, the computational graph/expression DAG will not. The same reasoning also applies to symbolic differentiation (Myth 2 and 3).

5 Conclusion

We have shown in this note that forward mode automatic differentiation and symbolic differentiation are algorithmically equivalent, i.e., they both perform the same set of operations when computing derivatives. The big contribution of automatic differentiation is rather of conceptual nature. It introduced the surprising idea that one can compute the derivative of any computer program. While this is a natural, yet very smart idea in hindsight, coming up with it for sure was not trivial. It has also led to many insights and algorithmic approaches like reverse mode, edge elimination, etc., and to automatic differentiation tools that compute derivatives of even very complex computer programs.
