On the forces that cable webs under tension can support and how to design cable webs to channel stresses

March 4, 2019

Abstract
In many applications of Structural Engineering the following question arises: given a set of forces \( f_1, f_2, \ldots, f_N \) applied at prescribed points \( x_1, x_2, \ldots, x_N \), under what constraints on the forces does there exist a truss structure (or wire web) with all elements under tension that supports these forces? Here we provide answer to such a question for any configuration of the terminal points \( x_1, x_2, \ldots, x_N \) in the two- and three-dimensional case. Specifically, the existence of a web is guaranteed by a necessary and sufficient condition on the loading which corresponds to a finite dimensional linear programming problem. In two-dimensions we show that any such web can be replaced by one in which there are at most \( P \) elementary loops, where elementary means that the loop cannot be subdivided into subloops, and where \( P \) is the number of forces \( f_1, f_2, \ldots, f_N \) applied at points strictly within the convex hull of \( x_1, x_2, \ldots, x_N \). In three-dimensions we show that, by slightly perturbing \( f_1, f_2, \ldots, f_N \), there exists a uniloadable web supporting this loading. Uniloadable means it supports this loading and all positive multiples of it, but not any other loading. Uniloadable webs provide a mechanism for distributing stress in desired ways.

1 Introduction
One of the main goals of Structural Engineering is to find performing structures when one incorporates into the design a specific type of material or substructure. Many materials behave quite differently under tension or compression: concrete and masonry structures are two examples of materials that perform much better under compression. Some types of structures support also only specific loadings: a wire or cable, for example, can only support tension and not compression. Here we are interested in the case where one incorporates a material that works particularly well under tension so that a cable web is expected to be representative of the most performing structure to be used. Thus, we address the following problem: given a set of forces \( f_1, f_2, \ldots, f_N \) applied at prescribed points \( x_1, x_2, \ldots, x_N \), under what constraints on the forces does there exist a wire web (or truss structure) with all elements under tension that supports these forces? Note that the problem is identical if one is interested in the case where all elements are under compression. We are only interested in cable wires which can be modeled as a set of straight truss elements: we do not consider the case of catenary elements, see, e.g., [1, 2, 3, 16].

In the two-dimensional case, a complete answer to this problem is given by Theorem 1 in [13] in the special case where the prescribed points are vertices of a convex polygon. This theorem states that, in this case, a web exists if and only if the net torque going clockwise around any connected portion of the boundary is positive: for any sequence \( (x_i, x_{i+1}, \ldots, x_j) \) of consecutive vertices ordered clockwise (where \( x_k \) is identified with \( x_{k-N} \)) we have:

\[
\sum_{k=i}^{j} \det(x_k - x_i, f_k) \geq 0.
\] (1)

Furthermore, by using the Airy stress functions theory, a representative web is explicitly given that contains no closed loops (that is, there is no set of wires forming the boundary of a polygon). The reader is referred to [13] for details.

So the question now is: what happens when the points are not the vertices of a convex polygon or what happens in the three-dimensional case? Theorem 1.1 (see below), which is one of the main results of this paper, answers this question completely. To make the statement clear, let us first introduce some terminology that will be used throughout the paper:

Finite web: a collection \( W := ([x_i, x_j], [x_k, x_l], \ldots) \) of segments (or bars) where \( x_1, \ldots, x_M \) are a finite set of points called nodes.

Terminal nodes: the nodes \( X = (x_1, \ldots, x_N) \), \( N \leq M \), where the forces are applied.

Internal nodes: the remaining nodes, if any.

Admissible web stress state: when each bar \( [x_i, x_j] \) of the web is endowed with a non negative tension \( \sigma_{ij} \), we say that \( \sigma = (\sigma_{ij}, \sigma_{kl}, \ldots) \) is an admissible web stress state on \( W \) for the loading \( F \) at \( X \) if it is in equilibrium under the action of the forces \( F = (f_1, f_2, \ldots, f_N) \) applied at \( X = (x_1, x_2, \ldots, x_N) \). If there exists such an admissible stress state then the web \( W \) is said to support \( F \) at \( X \).

Unloadable webs: webs which support only one loading (up to a positive multiplicative constant).

Theorem 1.1 then reads as follows:

**Theorem 1.1. Existence of a web under tension**

Let \( \mathcal{A}_X \) be the cone of displacements \( U = (u_1, u_2, \ldots, u_N) \) at points \( X = (x_1, x_2, \ldots, x_N) \) defined by

\[
\mathcal{A}_X := \{ U \in (\mathbb{R}^d)^N : \forall 1 \leq i < j \leq N, \ (u_i - u_j) \cdot (x_i - x_j) \geq 0 \}.
\]

Then, the following condition

\[
\inf_{U \in \mathcal{A}_X} F \cdot U \geq 0
\]

is necessary and sufficient to ensure the existence of a finite web under tension that supports the loading \( F \) at points \( X \). In such a case, the web connecting the terminal points \( X \) pairwise supports the loading \( F \).

Section 2 is dedicated to the proof of Theorem 1.1 and related consequences, whereas Section 3 provides insights on the mechanical meaning of the theorem with special reference to the two-dimensional case. In general, from a mechanical point of view, the statement says that the work performed by \( F \) non negative for any (infinitesimal) displacements \( U \) corresponding to a global expansion of the system of points \( X \). Notice that condition (3) provides a characterization of the set \( \mathcal{A}_X \) of all the loadings \( F \) at points \( X \) which can be supported by some finite web as the solution to a finite dimensional linear programming problem. Moreover, Theorem 1.1 states that a web supporting the given loading is the one that connects the terminal points pairwise (see Example 1.1).

**Example 1.1.** Consider a balanced set of forces \( f_1, \ldots, f_N \) at points \( x_1, \ldots, x_N \) that are directed radially outwards from a central point \( x_0 \) (so that \( f_i = c_i(x_i - x_0) \) for some set of positive coefficients \( c_i \)). Note that the balance of forces implies that \( x_0 \) must belong to the convex hull of the points \( x_1, \ldots, x_N \).

![Figure 1](image-url)

Figure 1: In this example the forces \( F \) are directed radially outwards from a central point \( x_0 \) and so the web that connects the terminal points \( X \) to \( x_0 \) supports such a loading. Among all the webs that can support \( F \), Theorem 1.1 provides the web connecting the terminal points pairwise and in Example 1.1 we determine the stress state in each wire of such a web and we prove it is an equilibrium stress state.

Clearly, the web formed by the wires connecting the points \( x_1, \ldots, x_N \) to \( x_0 \), Figure 1(a), supports this loading: \( \sigma_{0i} := c_i \|x_i - x_0\|^{-1} \) is an admissible stress state on this web. But we can find another web which supports

---

1 By “admissible stress state” we mean an equilibrium state in which all bars are either in tension, or carrying no load. Thus, by “supporting”, we mean supporting with all bars either in tension, or carrying no load.

2 Notice that we solve this problem within the context of infinitesimal elasticity: examples of applications of the finite deformation theory to describe the geometric nonlinearity are given, for instance, by [6, 18, 17].
the same loading: indeed, the web that connects the points $x_1, \ldots, x_N$ pairwise, Figure 1(b), is suitable when endowed with the stress state $\sigma_{ij} = \|x_i - x_j\|c_{ij}(\sum_k c_k)^{-1}$, with the equilibrium condition

$$f_i + \sum_{j \neq i} \sigma_{ij} \frac{x_j - x_i}{\|x_j - x_i\|} = c_i (x_i - x_0) + c_i \left( \sum_k c_k \right)^{-1} \sum_j c_j (x_j - x_i)$$

being satisfied at each node $x_i$.

Section 4 focuses on another major topic of the paper, that is, on channeling or redistributing stresses: we are interested in webs able to channel forces in a controlled way. For example, if one considers, say, a bicycle wheel or a suspension bridge, then, a desired distribution of forces is usually achieved by appropriately tightening the spokes or cables (clearly, the layout of these substructures is also essential). By contrast here we seek to distribute stress through judicious choices of the geometry of the web.

Notice that distributing stresses in wires is quite different than distributing electrical currents in conducting wires. At a junction of more than two conducting wires one cannot tell in advance (without looking at the rest of the circuit) how much flow will be channeled into the different wires (this is an advantage if one wants the current to flow where most needed, a disadvantage if one wants to control the allocation of current, as in an irrigation system). This is due to the fact that, in a conduction network, one only has to satisfy Kirchhoff’s law which states that the outgoing current has to balance the incoming current. By contrast, when distributing stresses, one has that at a node where four noneplanar wires join (for the three-dimensional case, or three for the two-dimensional case), balance of forces implies that the tension in one wire, and the geometry of the junction, uniquely determines the tension in the other wires. Thus, having at each internal node a coordination number of four for the three-dimensional case, or three for the two-dimensional case, is important to uniquely determining the loading that a web can support. This principle underlies the construction of “pentamode materials” [14], which have a diamond-like structure with a coordination number of 4 at each node of the structure. As a consequence, the stress field is essentially uniquely determined: like fluids which only support a hydrostatic loading, pentamodes only support one loading but, unlike fluids, that loading can be a combination of hydrostatic and shear forces. Pentamode materials have been studied for their use in cloaking, in particular for cloaking against sonar. They can guide the acoustic wave around an object while having little impedance mismatch at the membrane boundary with the surrounding fluid [13].

Webs of springs that support only one loading (up to a multiplicative constant) were instrumental in [5,10]. The corresponding elastic energies have the form $(F \cdot U)^2$, when their terminal nodes have displacements $U = (u_1, u_2, \ldots, u_N)$, so that the webs are able to support only forces proportional to $F$. In that context, as the elastic energy can be expressed using a rank-one matrix in the form $U \cdot (F \otimes F) \cdot U$, such webs were called “rank-one webs”. In this paper, as we are interested in energies that are not necessarily quadratic, we prefer to use the definition of uniloadable webs. In Section 4 we establish that, apart from some exceptional cases, if forces $f_1, f_2, \ldots, f_N$ at prescribed points $x_1, x_2, \ldots, x_N$ are supported by one web, they are also supported by a uniloadable one.

The uniloadable networks we introduce here if prestressed could replace the pentamode materials in the aforementioned cloaking applications, allowing much greater flexibility in the design and economy in the number of junctions and wire elements.

One may not be interested only in uniloadable webs but more generally in webs $W$ for which the set $C_W$ of supported loadings is prescribed. It is clear that, for a given web $W$ with terminal nodes at $X$, the set $C_W$ is a convex cone contained in $A_X^\perp$. In Section 4 we show that the converse is true too in an approximate sense: given a convex cone $C \subset A_X^\perp$, one can find a sequence of webs $W_n$ such that $C_{W_n}$ approaches $C$ as $n \to \infty$. For two-dimensional webs where the points $X$ are the vertices of a convex polygon, a similar question was addressed in Theorem 2 of [13].

2 On the existence of a web under tension

This Section is dedicated to the proof of Theorem 1.1 and it contains some mathematical technicalities. Therefore, we recommend the reader who is more interested in the mechanical interpretation of the theorem to skip to Section 3.

Given a set of forces $F$ applied at the points $X$, we question the existence of a web supporting such a loading that has all the wires under tension. Recall that the equilibrium of a wire web is achieved if the tension is constant in each wire and if each node is in equilibrium. This situation admits a nice and synthetic, even if a bit abstract, formulation in terms of measures which is convenient for proving Theorem 1.1.
Given a web $W$, the associated measure is
\[ W := H^1_{[x_i, x_j]} + H^1_{[x_k, x_l]} + \ldots \] (4)
where $H^1_{[x_i, x_j]}$ stands for the line measure (the one dimensional Hausdorff measure) concentrated on the segment $[x_i, x_j]$. Accordingly the stress state $\sigma$ can be represented by the measure
\[ \mathcal{S} := \sigma_{ij} \frac{x_i - x_j}{|x_i - x_j|} \otimes \frac{x_i - x_j}{|x_i - x_j|} H^1_{[x_i, x_j]} + \sigma_{kl} \frac{x_k - x_l}{|x_k - x_l|} \otimes \frac{x_k - x_l}{|x_k - x_l|} H^1_{[x_k, x_l]} + \ldots \] (5)

Similarly, associated with the applied system of forces is the discrete measure
\[ F := \sum_{i=1}^{N} f_i \delta_{x_i} \] (6)

and the requirement that all wires be under tension is equivalent to the requirement that the measure $\mathcal{S}$ take values in the set of positive semi-definite symmetric matrices. We will denote with $\mathcal{M}^+$ the set of such measures. Using this formulation, searching for a finite web boils down to finding $\mathcal{S} \in \mathcal{M}^+$ of the form (5) such that (7) is satisfied.

If we drop the constraint that $\mathcal{S}$ must be of the form (5), we are led to an interesting generalization: a \textit{generalized web} $W$ is a positive measure, and it supports the loading $F$ if there exists some $\mathcal{S} \in \mathcal{M}^+$ absolutely continuous with respect to $W$ satisfying the equilibrium condition (7). The relation between this generalized formulation and the so-called Michell problem is provided in Section 2.3.

\subsection*{2.1 Proof of Theorem 1.1}

\textbf{Proof.} To prove that condition (3) is necessary, we consider an admissible web stress $\mathcal{S}$ for the loading $F$. As $\mathcal{S}$ is a positive semidefinite tensor-measure with compact support, by Green's generalized formula we have (see Section 6 of [13]):

\[ 0 \leq \left\langle \mathcal{S}, e(u) \right\rangle = -\left\langle \nabla \cdot \mathcal{S}, u \right\rangle = \left\langle F, u \right\rangle = F : U. \] (8)

for all $C^1$ fields $u$ such that $e(u) := (\nabla u(x) + (\nabla u(x))^T)/2$ is positive semidefinite. Now, let $U = (u_1, u_2, \ldots, u_N)$ be an element of $A_X$. For any $\kappa > 0$, Lemma 1 (see below) provides a Lipschitz extension $\tilde{u} : \mathbb{R}^d \to \mathbb{R}^d$ satisfying $\tilde{u}(x_\ell) = u_\ell$ and
\[ \forall (x, y) \in (\mathbb{R}^d)^2, \quad \left(\tilde{u}(x) - \tilde{u}(y)\right) \cdot (x - y) \geq -\kappa \|x - y\|^2. \] (9)

This extension field is differentiable a.e. and, at every point $x$ of differentiability, inequality (9) implies that $e(\tilde{u}) \geq -\kappa I$. In order to apply Green’s formula, we introduce a regularized field $u^\eta := \tilde{u} \ast \rho^\eta$, $\rho^\eta$ being a smooth convolution mollifier (i.e., non negative, supported in the ball of radius $\eta$, and such that $\int \rho^\eta = 1$). It can be readily checked that the strain $e(u^\eta)$ associated with $u^\eta$ is smooth and satisfies everywhere the inequality $e(u^\eta) \geq -\kappa I$. By applying (8) to the field $u = u^\eta + \kappa x$, we deduce that
\[ \sum_{i} f_i \cdot u^\eta(x_i) + \kappa \sum_{i} f_i \cdot x_i \geq 0. \]

As $u^\eta \to \tilde{u}$ uniformly on every compact set, we can pass to the limits $\eta \to 0$ and $\kappa \to 0$ in the last inequality to obtain the desired inequality $F : U \geq 0$ (see equation (3)).

To prove that condition (3) is sufficient, we consider $F$ such that $F : U \geq 0$ for any $u \in A_X$. The linear conditions $(u_i - u_j) \cdot (x_i - x_j) \geq 0$ can be rewritten in the form $F^{(i,j)} : U \geq 0$, where:

\[ F^{(i,j)} = (f_1^{(i,j)}, f_2^{(i,j)}, \ldots, f_N^{(i,j)}) \text{ with } f_{\ell}^{(i,j)} = \begin{cases} x_j - x_i & \text{if } \ell = i, \\ x_i - x_j & \text{if } \ell = j, \\ 0 & \text{otherwise.} \end{cases} \] (10)

Hence, thanks to Farkas Lemma [8], we know that $F$ is a linear combination of the linear forms $F^{(i,j)}$ with non negative coefficients:
\[ F = \sum_{1 \leq i < j \leq N} \lambda_{i,j} F^{(i,j)}, \quad \lambda_{i,j} \geq 0. \] (11)
It is then easy to check that the positive semidefinite symmetric tensor measure
\[
\mathcal{S} = \sum_{1 \leq i < j \leq N} \lambda_{i,j} \frac{(x_i - x_j) \otimes (x_i - x_j)}{\|x_i - x_j\|} H_1([x_i, x_j]),
\] (12)
is a possible web stress for the loading \( \mathcal{F} \). Indeed, for any \( a \) and \( b \) in \( \mathbb{R}^d \), we have
\[
\nabla \cdot ((b - a) \otimes (b - a) H_1([a,b])) = |b - a| |(b - a)(\delta_a - \delta_b)|, \text{ thus } \nabla \cdot \mathcal{S} = -\sum_i \delta_i \delta_{x_i} = -\mathcal{F}. \] Let us emphasize that this web stress measure involves only the original nodes \((x_1, x_2, \ldots, x_N)\) as claimed in the theorem. \( \square \)

We now state and prove the interpolation lemma which was needed in the previous proof.

**Lemma 1. Interpolation Lemma**

Let \( A \) be a finite subset of \( \mathbb{R}^d \), and \( u : A \to \mathbb{R}^d \) the field satisfying \( (u(x) - u(y)) \cdot (x - y) \geq 0, \forall (x, y) \in A^2 \). Then, for any \( \kappa > 0 \) there exists a Lipschitz extension \( \tilde{u} \) of \( u \) on \( \mathbb{R}^d \) satisfying
\[
\forall (x, y) \in (\mathbb{R}^d)^2, \quad \langle \tilde{u}(x) - \tilde{u}(y), (x - y) \rangle \geq -\kappa \|x - y\|^2. \] (13)

**Proof.** As \( u \) is bounded on the bounded set \( A \), there exists \( M \) such that, for any \( x \in A, \|u(x)\| \leq M \) and \( \|x\| \leq M \). Moreover, as \( A \) is finite, there exists \( \delta > 0 \) such that, for any distinct points \( x \) and \( y \) in \( A \), \( \|x - y\| \geq \delta \). We set \( \lambda = \frac{\kappa M^2}{\delta^2} \) and choose \( s \) such that \( 0 < \lambda s < \min(\kappa, 1) \). Let us consider \( \phi \) defined on \( A \) by
\[
\phi(x) = (1 - \lambda s^2)x - su(x). \] (14)

For any distinct points \( x \) and \( y \) in \( A \), we have, by straightforward computation
\[
\|\phi(x) - \phi(y)\|^2 = \| (1 - \lambda s^2)(x - y) - s(u(x) - u(y)) \|^2
\]
\[
= \| (x - y) - s(u(x) - u(y)) + \lambda s(x - y) \|^2
\]
\[
= \|x - y\|^2 + s^2 \|u(x) - u(y)\|^2 + 2s \langle (x - y), (u(x) - u(y)) \rangle + \lambda^2 s^2 \|x - y\|^2
\]
\[
\leq \|x - y\|^2 + (1 - \lambda s^2) \|u(x) - u(y)\|^2 - 2\lambda s^2 \|x - y\|^2
\]
\[
\leq \|x - y\|^2 + 2M^2 \|u(x)\|^2 + 2M^2 \|u(y)\|^2 - 2\lambda s^2 \|x - y\|^2
\]
\[
\leq \|x - y\|^2 + 16M^2 s^2 - 2\lambda \delta^2 s^2
\]
\[
\leq \|x - y\|^2. \] (15)

Kirsbraun’s Theorem [11] proves the existence of an extension \( \tilde{\phi} \) of \( \phi \) on \( \mathbb{R}^d \) satisfying the same condition: for any \( (x, y) \in (\mathbb{R}^d)^2 \),
\[
\| \tilde{\phi}(x) - \tilde{\phi}(y) \| \leq \| x - y \|. \] (16)

Let us now define \( \tilde{u} \) on \( \mathbb{R}^d \) by setting
\[
\tilde{u}(x) = \frac{(1 - \lambda s^2)x - \tilde{\phi}(x)}{s}. \] (17)

For any \( x \in A \) we have \( \tilde{u}(x) = u(x) \). Moreover \( \tilde{u} \) is a Lipschitz function which satisfies
\[
(\tilde{u}(x) - \tilde{u}(y)) \cdot (x - y) = s^{-1} \left( (1 - \lambda s^2) \|x - y\|^2 - (\tilde{\phi}(x) - \tilde{\phi}(y)) \cdot (x - y) \right)
\]
\[
\geq -\lambda s \|x - y\|^2 \geq -\kappa \|x - y\|^2. \] (18)

\( \square \)

### 2.2 Support of the stress field

From a physical viewpoint it seems obvious that a finite web supporting the loading \( \mathcal{F} \) at the points \( X = (x_1, x_2, \ldots, x_N) \) should have an associated stress measure vanishing outside the convex hull of the points \( x_1, x_2, \ldots, x_N \). This section is devoted to proving this fact which turns out to be valid also for generalized webs.

---

3Physically, when \( s \) is small, we can think of \( \phi(x) \) as a deformation \( x \to \phi(x) \) associated with the displacement field \( u(x) \). The additional uniform contractive factor of \((1 - \lambda s^2)\) is needed to account for the finite deformation corrections when \( u(x) - u(y) \) is perpendicular to \( x - y \) (with say \( u(y) = 0 \) and \( y = 0 \), and \( u(x) \) orthogonal to \( x \), the distance \( |x - su(x)| \) lengthens as \( s \) is increased).
Theorem 2.1. Let \( F \) be a vector measure with compact support \( K \) and \( \mathcal{G} \) in \( \mathcal{M}^+ \) such that \( \nabla \cdot \mathcal{G} + F = 0. \) Then the support of \( \mathcal{G} \) is contained in the convex envelope \( \text{co}(K) \) of \( K. \)

Notice that, from this result, we can deduce that the support of \( \mathcal{G} \) is contained in the subspace spanned by the vectors \( x_1, x_2, \ldots, x_N \) and thus that the loading forces \( f_i \) belong to this subspace. Hence, we will be able to reduce our problem to this subspace and assume without loss of generality that \( x_1, x_2, \ldots, x_N \) span \( \mathbb{R}^d. \)

Proof. By Hahn-Banach separation theorem \([7]\), proving that \( \mathcal{G} \) vanishes outside the convex envelope \( \text{co}(K) \) of \( K \) reduces to checking that \( \mathcal{G} \) vanishes on all half spaces \( P_{m,a} := \{ x : x \cdot m > a \} \) with \( a \in \mathbb{R} \) and \( m \in S^{d-1} \) which do not intersect \( K. \) This verification is achieved in several steps. We first remark that, as \( P_{m,a} \) and \( K \) do not intersect, we have \( \nabla \cdot \mathcal{G} = 0 \) on \( P_{m,a}. \)

**Step 1:** Let us consider first a field \( \tilde{\mathcal{G}} \in C^1(\mathbb{R}^d, \mathbb{R}^d_{sym}) \) such that \( \tilde{\mathcal{G}} \geq 0 \) and \( \nabla \cdot \tilde{\mathcal{G}} = 0 \) on \( P_{m,a}. \) Without loss of generality assume that \( m = e_1, \) where \( e_1 \) is the unit vector along the \( x_1 \)-axis (where \( x_1 \) is not to be confused with the point \( x_1). \) Let us apply Green’s formula in the half ball \( \Omega_R := \{ x : x_1 > a, |x| < R \}. \) We have

\[
\int_{\partial \Omega_R} (\tilde{\mathcal{G}} \cdot e_1) \cdot n dH^{d-1} = \int_{\Omega_R} (\nabla \cdot \tilde{\mathcal{G}}) \cdot e_1 dH^d = 0,
\]

where \( n \) stands for the outward normal. Dividing the boundary \( \partial \Omega_R \) into \( \Sigma_R := \{ x : x_1 = a, |x| < R \} \) and \( S_R := \{ x : x_1 > a, |x| = R \} \) we get

\[
-\int_{\Sigma_R} (\tilde{\mathcal{G}} \cdot e_1) \cdot e_1 dH^{d-1} + \int_{S_R} (\tilde{\mathcal{G}} \cdot e_1) \cdot n dH^{d-1} = 0.
\]

Thus we have

\[
\int_{S_R} (\tilde{\mathcal{G}} \cdot e_1) \cdot e_1 dH^{d-1} \leq \int_{S_R} |\tilde{\mathcal{G}}| dH^{d-1}.
\]

As \( \tilde{\mathcal{G}} \in L^1, \int_0^\infty (\int_{S_R} |\tilde{\mathcal{G}}| dH^{d-1}) dR < +\infty \) and so there exists a sequence \( R_n \to +\infty \) such that

\[
\int_{S_R} |\tilde{\mathcal{G}}| dH^{d-1} \to 0.
\]

This implies that

\[
\lim_{n \to \infty} \int_{S_R} (\tilde{\mathcal{G}} \cdot e_1) \cdot e_1 dH^{d-1} = 0.
\]

(22)

As \( (\tilde{\mathcal{G}} \cdot e_1) \cdot e_1 \geq 0 \) we get \((\tilde{\mathcal{G}} \cdot e_1) \cdot e_1 = 0\) on the whole hyperplane \( \{ x : x_1 = a \}. \) As \( \tilde{\mathcal{G}} \geq 0, \) we deduce that \( (\tilde{\mathcal{G}} \cdot e_1) \cdot e_1 = 0 \) on this hyperplane.

**Step 2:** We remark that, if \( \tilde{\mathcal{G}} \geq 0 \in C^1(\mathbb{R}^d, \mathbb{R}^d_{sym}) \) satisfies \( \nabla \cdot \tilde{\mathcal{G}} = 0 \) on the whole space \( \mathbb{R}^d, \) then by applying the result of step 1 to every pair \((m,a) \in S^{d-1} \times \mathbb{R}^d\) we get \( \tilde{\mathcal{G}} = 0 \) everywhere. We also remark that this result holds true for any space dimension \( d. \)

**Step 3:** Going back to the case where \( \tilde{\mathcal{G}} \geq 0 \in C^1(\mathbb{R}^d, \mathbb{R}^d_{sym}) \) satisfies \( \nabla \cdot \tilde{\mathcal{G}} = 0 \) only on the half space \( P_{m,a}, \) we apply Step 1 to every pair \((m,t) \) with \( t > a \) and we deduce that \( \tilde{\mathcal{G}} \cdot m = 0 \) on the hyperplane \( \Sigma_t := \{ x : x \cdot m = t \}. \) The restriction of \( \tilde{\mathcal{G}} \) to this hyperplane is tangential and divergence free. For almost every \( t > a, \int_{\Sigma_t} |\tilde{\mathcal{G}}| < +\infty, \) by applying the result of Step 2 to \( \mathbb{R}^d, \) we deduce that \( \tilde{\mathcal{G}} \) vanishes on almost all hyperplanes \( \Sigma_t. \) Hence, \( \tilde{\mathcal{G}} \) vanishes on \( P_{m,a}. \)

**Step 4:** In order to extend this result to measures, we introduce a smooth mollifier \( \rho^\eta \) and \( \mathcal{G}^\eta := \mathcal{G} \ast \rho^\eta. \) Clearly \( \mathcal{G}^\eta \) belongs to \( L^1 \cap C^\infty(\mathbb{R}^d_{sym}), \) \( \mathcal{G}^\eta \geq 0 \) and, for any \( t > a, \) and for \( \eta \) small enough we have \( \nabla \cdot \mathcal{G}^\eta = 0 \) on \( P_{m,t}^+. \) By applying the result of Step 3 to \( \mathcal{G}^\eta \) we get \( \mathcal{G} = 0 \) on \( P_{m,t}^+. \) and by passing to the limit \( \eta \to 0 \) we get \( \tilde{\mathcal{G}} = 0 \) on \( P_{m,t}^+. \) The theorem is proven by passing finally to the limit \( t \to a. \) \( \square \)

2.3 Link with the Michell problem

A very old problem in Mechanical Engineering consists in minimizing the total volume of a network of elastic bars (trusses) while the resistance to a given load remains constant. It reduces to a linear programming problem which, according to our notation, reads:

\[
\inf_{\sigma} \left\{ \sum_i \sum_j |\sigma_{ij}| \|x_j - x_i\| : f_i + \sum_{j \neq i} \sigma_{ij} \frac{x_j - x_i}{\|x_j - x_i\|} = 0, \forall i \right\}
\]

Here we choose \( x_1 \) as the origin for identifying points and vectors.
The classical dual formulation is the following maximization problem on deformations:

$$\sup_u \left\{ \sum_i f_i \cdot u_i : \|(u_i - u_j) \cdot (x_i - x_j)\| \leq \|(x_i - x_j)\|^2, \forall i \neq j \right\}$$  \hspace{1cm} (24)

As no assumption is made on the number of bars, this belongs to the class of topological optimization problems and it is well known that, in general, no optimal solution exists. Indeed, during the optimization process, the number of bars may increase to infinity leading thus to diffuse structures. The crucial contribution of Michell in the 1900’s was to formulate a generalized version (called Michell problem) in order to take into account all possible structures which may appear in the limit. In the generalized version, attention is focused on the stress carried by the structure rather than on its geometry. Michell stated a duality principle and obtained the optimality conditions on the stress and strain tensors: they share the same eigenvectors (principal directions) and the eigenvalues of the strain tensor have a fixed absolute value. Moreover, Michell noticed that, in the two-dimensional case, when the eigenvalues of the strain tensor have opposite sign and when the eigenvector fields are smooth enough to define stream lines (called “lines of principal action”), then these lines constitute a so-called Hencky-net. This is a family of orthogonal curves which represents the limit of the families of bars through the optimization process. We refer to [4] for a detailed mathematical study where optimality conditions for a generalized truss are established in a rigorous way. The generalized stress formulation derived by Michell in dimension \(d = 2\) reads as follows:

$$\inf_{\mathcal{S}} \left\{ \int_\Omega \rho_0(\mathcal{S}) : \nabla \cdot \mathcal{S} + \mathcal{F} = 0 \right\}$$  \hspace{1cm} (25)

where \(\rho_0(\mathcal{S}) := |\lambda_1(\mathcal{S})| + |\lambda_2(\mathcal{S})|\) denotes the sum of the moduli of the two principal values of \(\mathcal{S}\). The corresponding dual problem reads:

$$\sup_{\mathcal{S}} \{<F, \tilde{u} > : |(\tilde{u}(x) - \tilde{u}(y)) \cdot (x - y)| \leq |x - y|^2\}$$  \hspace{1cm} (26)

An admissible pair \((u, \mathcal{S})\) is then optimal if and only if the following extremality relation holds (see [4]):

$$<F, u> = \int_\Omega \rho_0(\mathcal{S}) \, dx.$$  \hspace{1cm} (27)

We can now emphasize the link between our problem and the Michell problem described above. It turns out indeed that admissible stress states associated with a loading \(F\) in the cone \(\mathcal{A}_X^2\) are solutions of the Michell problem.

**Theorem 2.2.** Let \(F\) be a bounded vector-measure with compact support \(K\) and \(\mathcal{S} \geq 0\) in \(M_{sym}^2\) such that \(\nabla \cdot \mathcal{S} + \mathcal{F} = 0\). Then

i) \(\mathcal{S}\) is a solution to the Michell problem for \(F\),

ii) any solution \(\tilde{\mathcal{S}}\) to the Michell problem for \(F\) satisfies \(\tilde{\mathcal{S}} \geq 0\).

**Proof.** Clearly \(u(x) := x\) is admissible for the dual problem. As \(-\nabla \cdot \mathcal{S} = F\), the following relation holds:

$$<F, x> = <-\nabla \cdot \mathcal{S}, x> = <\mathcal{S}, \nabla x> = \int \text{Tr}(\mathcal{S}).$$  \hspace{1cm} (28)

If we assume that \(\mathcal{S} \geq 0\), then Michell's dual energy \(\rho_0(\mathcal{S})\) coincides with \(\text{Tr}(\mathcal{S})\) as both \(\lambda_1(\mathcal{S})\) and \(\lambda_2(\mathcal{S})\) are non-negative. In particular, we have \(\int \rho_0(\mathcal{S}) = \int \text{Tr}(\mathcal{S}),\) hence by (28) the pair \((x, \mathcal{S})\) satisfies relation (27). The optimality of \((x, \mathcal{S})\) follows. This proves point i).

To prove point (ii), it is enough to notice that, for any other solution \(\tilde{\mathcal{S}}\) of the primal problem, the couple \((x, \tilde{\mathcal{S}})\) is optimal and thus must satisfy the optimality condition (27) so that, by (28), one has

$$<F, x> = \int \text{Tr}(\tilde{\mathcal{S}}) \, dx = \int \rho_0(\tilde{\mathcal{S}}) \, dx.$$

As \(\rho_0(\tilde{\mathcal{S}}) \geq \text{Tr}(\tilde{\mathcal{S}})\), we deduce that \(\rho_0(\tilde{\mathcal{S}}) = \text{Tr}(\tilde{\mathcal{S}})\) and so \(\tilde{\mathcal{S}} \geq 0\). \(\square\)

### 3 Theorem 1.1 in two dimensions

To get a better insight on the mechanical interpretation of the statement of Theorem 1.1, we focus on the two-dimensional case which was also analyzed in [13]. In particular, we will show that when the points \(x_1, x_2, \ldots, x_N\) are vertices of a convex polygon, our condition \(3\) is a generalization of the condition \(1\) proved in [13].

3.1 Mechanical interpretation of the extreme rays of the cone $\mathcal{A}_X$

Given a set of points $x_1, x_2, \ldots, x_N$ that are vertices numbered clockwise of a convex polygon, let us consider the following displacement field $u_k^{(j,i)}$ defined by:

$$u_k^{(j,i)} = \begin{cases} -R_\perp(x_k - x_j), & \text{for } k = j, j + 1, \ldots, i - 1, \\ 0 & \text{otherwise}, \end{cases}$$

(29)

where

$$R_\perp = \begin{bmatrix} 0 & 1 \\ -1 & 0 \end{bmatrix}$$

(30)

is the matrix for a 90° clockwise rotation and, if necessary, we identify $k$ with $k - N$. We call $u_k^{(j,i)}$ a “clam-shell” displacement (see [2]) as it corresponds to the infinitesimal rotation between two non-overlapping subpolygons of the polygon of terminal points can be divided into: by keeping fixed one of the two subpolygons, the rotation of the other opens the clam. Given any points $x_k$ and $x_\ell$ on opposite sides of the clam (where $u_k^{(j,i)} \neq 0$, while $u_\ell^{(j,i)} = 0$) we have

$$(u_k^{(j,i)} - u_\ell^{(j,i)}) \cdot (x_k - x_\ell) = -[R_\perp (x_k - x_j)] \cdot (x_k - x_\ell) \geq 0,$$

(31)

where the last inequality follows from the convexity of the polygon and the clockwise numbering of the points. Thus, this clam-shell movement is an admissible displacement as it satisfies (2). This implies that $F$ satisfies the constraints (3), that is,

$$0 \leq \sum_{k=1}^{N} f_k \cdot u_k^{(j,i)} = \sum_{k=j}^{i-1} (x_k - x_j) \cdot [R_\perp f_k],$$

(32)

which are precisely the same as the constraints (1) that characterize $\mathcal{A}_X^*$, that is the set of all the loadings $F$ at $X$ which can be supported by a finite web. Thus, in this case of the $x_i$ forming the vertices of a convex polygon, the displacements $U$ correspond precisely (up to an infinitesimal rigid body motion) to these “clam-shell” movements, and do not include any other movements.

![Figure 2: Given a set of points $x_1$ that form the vertices of a convex polygon, in (a), an extremal infinitesimal movement is obtained by breaking the polygon into two non-overlapping subpolygons connected at one vertex $x_i$, as in (b). The “clam-shell” movement then consists of fixing one subpolygon, in this example the lower subpolygon away from any vertex $x_k$, so the “clam” opens slightly, thus moving any vertex $x_k$ on the upper subpolygon away from any vertex $x_\ell$ on the lower subpolygon.](image)

More generally, to check the criterion (3) it suffices to check it for those $U$ corresponding to the extreme rays $U^m$ of the cone $\mathcal{A}_X$. These rays are perpendicular to the “faces” of the polar cone $-\mathcal{A}_X^*$ (see Figure 3). We use an integer $m = 1, 2, \ldots, M$ to index these rays. For any given $m$ there exist associated loadings $F_h^m$, $h = 1, 2, \ldots, D - 1$ all perpendicular to the extreme ray indexed by $m$. Here, for a given $m$, each value of $h$ signifies a pair $(i, j) = (i(h,m), j(h,m))$ such that $F_h^m = F^{(i,j)}$, and linear combinations of the $F_h^m$, $h = 1, 2, \ldots, D - 1$ with positive weights generate the “face” perpendicular to the extreme ray of the cone $\mathcal{A}_X$. Let $U^m = (u_1^m, u_2^m, \ldots, u_N^m)$ be on this extreme ray. Then, we have

$$F_h^m \cdot U^m = 0, \text{ for } h = 1, 2, \ldots, D - 1.$$

(33)

In particular, if $F_h^m = F^{(i(h,m), j(h,m))}$, then the orthogonality implies that

$$(u_i^m - u_j^m) \cdot (x_i(h,m) - x_j(h,m)) = 0.$$

(34)

If we think of $U^m$ as corresponding to a displacement, then this restriction says (within the infinitesimal displacements framework) there is no change in distance between $x_i(h,m)$ and $x_j(h,m)$: the constraint is equivalent.
Figure 3: Schematic illustration of the cone $\mathcal{A}_X$ and the polar cone $-\mathcal{A}_X^*$, the negative of the dual cone $\mathcal{A}_X^*$. Here the $F^{(i,j)}$ are the extreme rays of the dual cone $\mathcal{A}_X^*$, while the $U^m$ are the extreme rays of the cone $\mathcal{A}_X$.

to only allowing those deformations compatible with rigid rods joining the pairs of points $(x_{i(h,m)}, x_{j(h,m)})$ for $h = 1, 2, \ldots, D - 1$. After eliminating the trivial infinitesimal rigid body motions (translations and rotations) from $U^m$, by requiring it to satisfy, for instance,

$$\sum_{i=1}^N u_i = 0, \quad \sum_{i=1}^N x_i \cdot A u_i = 0$$

(35)

with $A$ any $d \times d$ antisymmetric matrix, there still must be one degree of freedom associated with the infinitesimal motion corresponding to $U^m$. The equality $(u_i - u_j) \cdot (x_i - x_j) = 0$ cannot hold for all $i \neq j$ as this then would correspond to a trivial overall (infinitesimal) rigid body motion, which must be zero by (35). To fix the one-degree of freedom, we can impose the normalization condition that $U^m \cdot X = 1$. Without loss of generality this can be seen by noting that for any $U \in \mathcal{A}_X$,

$$0 \leq \sum_{i,j=1}^N (u_i - u_j) \cdot (x_i - x_j) = \sum_{i,j=1}^N u_i \cdot u_i + u_j u_j - 2 \sum_{i=1}^N u_i \sum_{j=1}^N u_j = 2U \cdot X$$

(36)

where, to get the last equality, we use (35). Furthermore, $U \cdot X = 0$ implies that $U$ is a rigid body motion, which we excluded. So $U \cdot X > 0$, and by replacing $U$ with $U/(U \cdot X)$ we see that we can assume $U \cdot X = 1$.

To conclude, we showed that if the terminal points are the vertices of a convex polygon, then all the extremal displacements correspond to clam-shell movements but notice that if there is at least one terminal point inside the convex hull of the terminal points, then besides clam-shell movements there are also other types of displacements, as shown in Figure 4.

### 3.2 Simplifying the two-dimensional web

In two dimensions, in any web, we define a loop to be any polygon such that its edges are the wires of the web. A minimal loop is one with no other wires inside the polygon. Any web with all pairs of terminal points interconnected, as in Figure 1 (b), can then be replaced by an equivalent one with at most $P$ minimal loops where $P$ is the number of points $x_1, \ldots, x_N$ that lie inside the convex hull of these $N$-points. To show this we first place internal nodes where any pair of wires $(x_i, x_j)$ and $(x_r, x_s)$ cross. Then take any minimal loop in the network. The vertices of this loop may include a terminal point $x_j$ so long as the net force acting on the loop at $x_j$ (including $f_j$ and the forces acting on $x_j$ due to the tension in the other wires outside the loop) points outside the loop. As the wires are all under tension, the loop then is necessarily convex and exerts forces $-f_m'$ at the nodes numbered clockwise around the loop. These forces necessarily satisfy (1), and the loop can be replaced by an open web. The number of minimal loops in the web is thus reduced by one. This procedure can be continued until there are at most $P$ minimal loops, and each of these loops is non-convex and thus its vertices include at least one terminal node $x_i$ where the associated force $f_j$ points inside the loop. Video1 (see Supplementary Material) shows an example of a web whose wires connect all the terminal points pairwise (initial frame), and how to replace each closed loop with an open web so that the final frame represents an equivalent web in which there is only one minimal loop due to the presence of one point, $x_4$, inside the convex hull of the terminal points.
We first focus on the case where \( F \) is not simply a ray but a convex cone. Specifically, we will give a positive answer in the following asymptotic case. By cleaving the top of this cone, creating a polygonal face (Figure 5(c)), one obtains an associated web (Figure 5).}

In two dimensions the procedure for replacing a junction with \( M > 4 \) wires is more complicated. Here we provide a procedure to achieve such a goal in \( 
\begin{align*}
\text{Figure 4: Consider the following 4 points which form an arrowhead in the plane: } & \ x_1 = [0; 0], \ x_2 = [1; 1], \ x_3 = [0.5; 0], \text{ and } x_4 = [1; -1]. \text{ The displacements corresponding to the extreme rays of the cone } A_X \text{ for this special geometry can be divided into two groups: clam-shell movements and non-clam-shell movements. In this figure, the black lines represent the rigid wires and the green lines represents the deformable bonds. Clearly, (a) is an example of a non-clam-shell displacement, whereas (b) is an example of a clam-shell displacement (the rigid wire connecting the points } x_1 \text{ and } x_2 \text{ can rotate infinitesimally about the point } x_2 \text{ while the rigid triangle formed by } x_2, x_3, \text{ and } x_4 \text{ is held fixed). Notice that the existence of non-clam-shell movements is due to the fact that the point } x_3 \text{ does not belong to the convex hull of the terminal points.}
\end{align*}
\]
we pick 4 of the wires (those marked in blue in Figure 6(a)), and points \( x_1, x_2, x_3 \) and \( x_4 \) on the four wires such that the tetrahedron \( T \) formed by \( x_1, x_2, x_3 \) and \( x_4 \) encloses the junction, which without loss of generality can be taken to be at the origin \( x_0 = 0 \). (This requires that the four wires be chosen so that they do not all lie on one side of any plane through the origin: balance of forces at the origin ensures that at least one choice of such four wires exists). The tensions in these four wires generally do not balance. However, consider the “tensegrity network” consisting of rods from the origin to the points \( x_1, x_2, x_3 \) and \( x_4 \) under compression, balanced by wires along the edges of the tetrahedron \( T \) that are under tension. Example 1.1 (see Section 1) gives the explicit solution for the compressive forces in the rods and the tensions in the wires in this “tensegrity network”. We next superimpose this “tensegrity network” on our junction with the tensions in the “tensegrity network” scaled so after superposition the tension near the junction in one wire cancels, while the tension in the other wires remain nonnegative, as sketched in Figure 6(b). We thus obtain a web under tension where the number of wires joined to the origin is now \( M = 1 \) or less. However, we typically have also created junctions, at some of the points \( x_1, x_2, x_3 \) and \( x_4 \) where 5 wires meet, like those in Figure 6(c). These junctions are rather special in that one wire goes straight through the junction (but typically has different tensions on opposite sides of the junction). These junctions are then locally replaced by networks in which at most four wires meet as illustrated in Figure 6(d). Lemma 2 below guarantees this can be done. The last step is to successively repeat the argument until the junction at the origin has at most 4 wires.

**Lemma 2. The five wires problem**

Consider five wires with tensions \( T_i > 0 \), directions \( \mathbf{v}_i \) and joining at the origin \( \mathbf{x} = \mathbf{0} \). Assume that the three first directions are independent while \( \mathbf{v}_5 = -\mathbf{v}_4 \). Then we can replace these wires by a web in tension such that at each of its nodes, no more than 4 wires are joining.

**Proof.** We can assume without loss of generality that \( T_5 = \alpha T_4 \) so that balance of forces implies that \( T_1 \mathbf{v}_1 + T_2 \mathbf{v}_2 + T_3 \mathbf{v}_3 + (1 - \alpha) T_4 \mathbf{v}_4 = 0 \). Set \( t > 0 \) and \( s > \frac{\alpha}{2} \). Set also \( x_1 = t \mathbf{v}_1 \), \( x_2 = t \mathbf{v}_2 \), \( x_3 = t \mathbf{v}_3 \), \( x_4 = t s T_4 \mathbf{v}_4 \) and \( x_5 = -t r T_4 \mathbf{v}_4 \) where \( r := \frac{s}{3s - \alpha} \). As the real parameter \( t \) can be arbitrarily chosen provided it is small enough, then we can avoid creating new nodes where a node already exists or where a wire lies. The parts of the wires which lie between the points \( x_i \) and the origin are replaced by six wires \([x_i, x_4], [x_i, x_5] \) \( i \in \{1, 2, 3\} \). When these wires have respective (positive) tensions

\[
T_{i4} = \frac{r}{t(r + s)} \|x_i - x_4\|, \quad T_{i5} = \frac{s}{t(r + s)} \|x_i - x_5\|, \quad i \in \{1, 2, 3\},
\]

the web is in equilibrium. Indeed at each node \( x_i \) for \( i \in \{1, 2, 3\} \) we have

\[
T_{i4} \frac{x_4 - x_i}{\|x_i - x_4\|} + T_{i5} \frac{x_5 - x_i}{\|x_i - x_5\|} + T_i \mathbf{v}_i = \frac{rs - sr}{t(r + s)} t T_4 \mathbf{v}_4 + \frac{r + s}{t(r + s)} (-t T_4 \mathbf{v}_4) + T_i \mathbf{v}_i = 0.
\]

Moreover, at nodes \( x_4 \) and \( x_5 \) we have

\[
\sum_{i=1}^{3} \left(T_{i4} \frac{x_i - x_4}{\|x_i - x_4\|}\right) + T_4 \mathbf{v}_4 = \frac{1}{r + s} \left(r \alpha + s - 3rs\right) T_4 \mathbf{v}_4 = 0.
\]
Figure 6: Steps in the replacement of a junction of many wires under given balanced tensions, with a network localized around the junction such that at most 4 wires meet at any junction in the new network, and the network still supports the same tensions in the wires meeting the network.

\[ \sum_{i=1}^{3} \left( T_{ij} \frac{x_i - x_5}{\|x_i - x_5\|} \right) + T_5 v_5 = \frac{1}{r + s} \left( -s - ar + 3rs \right) T_4 v_4 = 0. \]  \hspace{1cm} (40)

4.2 Uniloadable webs

Given a ray \( C \subset A^*_X \), we want to determine whether there exists a uniloadable web which can support the corresponding loading \( \lambda F \), with \( \lambda \geq 0 \). In case \( C \) does not belong to the interior of the cone \( A^*_X \), then the existence of a uniloadable web is not guaranteed. When \( F \) belongs to the interior of \( A^*_X \), then we prove the existence of a uniloadable web supporting such a loading (up to a multiplicative constant).

4.2.1 Stuck loadings

Let us start with the following remark: let \( F = (f_1, \ldots, f_N) \) belong to \( A^*_X \) with \( X = (x_1, \ldots, x_N) \). Then, it also belongs, for any \( t \geq 0 \), to the admissible loading cone \( A^*_{X+tF} \) of the shifted points \( (x_1 + tf_1, \ldots, x_N + tf_N) \). Indeed, taking a web \( W \) which supports \( F \) at \( X \) and adding to \( W \) all the wires \( [x_i, \tilde{x}_i] \) leads clearly to a web supporting \( F \) at \( X + tF \). When \( t < 0 \) things are less clear. We say that \( F \) at \( X \) is an unstuck loading if there exists \( \varepsilon > 0 \) such that \( \forall 0 < t < \varepsilon, F \in A^*_{X-t\tilde{F}} \), otherwise we say that \( F \) is a stuck loading. A particular case of stuck loadings, referred to as completely stuck loadings, is when there exist some \( k \in \{1, \ldots, N\} \) and \( \varepsilon > 0 \) such that

\[ \forall 0 < t < \varepsilon, F \notin A^*_{X} \text{ with } \tilde{X} = (x_1, \ldots, x_{k-1}, x_k + tf_k, x_{k+1}, \ldots, x_N). \]

The stuck or completely stuck conditions can only occur when the loading \( F \) is a ray on the boundary of the cone of admissible loadings \( A^*_X \), as we will prove in the next subsection that any \( F \) in the interior of \( A^*_X \) is unstuck. For a better insight, let us consider two examples of completely stuck loadings.

Example 4.1. Consider forces \( f_1 = [-1; 0], f_2 = [3/4; 1], f_3 = [3/4; -1], \) and \( f_4 = [-1/2; 0] \) at the four points considered in Figure 3 that is, \( x_1 = [0; 0], x_2 = [1; 1], x_3 = [1; -1], \) and \( x_4 = [1/2; 0] \). They are supported by the web in Figure 7(a).

Our objective is to show that this is the only web supporting these forces, thus implying that the loading is “completely stuck”. First move the force \( f_4 = [-1/2; 0] \) back to the origin, by attaching a wire joining the origin to \( x_4 \), as in Figure 7(b). Then the net force acting on the origin is \([-3/2; 0]\) and is balanced by the forces \( f_1 \) and
Figure 7: Examples of webs with “completely stuck loadings” in two dimensions. We argue in Example 4.1 that (a) is the unique web that supports the given forces at the terminal nodes. A wire can be attached to the node $x_4$, as in (b), in order to uniquely define the associated Airy stress function, up to the addition of an affine function. This Airy stress function then lies above the triangular pyramidal Airy stress function associated with the net forces applied at the three points $x_1$, $x_2$, and $x_3$, as in (c). At the same time it must have a discontinuity in slope across the line between $x_1$ and $x_4$ corresponding to the tension in the wire joining those two points. This then uniquely determines the Airy stress function (modulo the addition of an affine function) and thus uniquely determines the web. Figure (d), as discussed in Example 4.2, provides another example of a web with a “completely stuck loading” where the web is uniquely determined once the loading is specified.

The open web in Figure 7(c) supports these three forces, and the associated Airy function (up to addition of an affine function, see also [9]) is

$$\phi_L(x) = \max\{-3|x_2|/4, 1/4 - x_1\},$$

(41)

where $x_1$ and $x_2$ are the coordinates of $x$.

Now suppose we have any web supporting the four forces $f_1$, $f_2$, $f_3$, and $f_4$. Necessarily this web will be confined within the convex hull of the three points $x_1, x_2, x_3$. To define the associated Airy stress potential, in say all of $\mathbb{R}^2$, we need to move the four forces to infinity by attaching infinite wires to the four points in the direction of infinity (the wire attached to $x_1$ overlaps the wire attached to $x_4$ left of the origin). The existence of these wires implies a discontinuity of slope of the Airy stress function across them, matching the tension in the wire. Now consider the Airy stress function in the vicinity of the point $x_4$. In particular take the tangent plane at a point $x_0$ that approaches $x_4$ from the left remaining infinitesimally above the wire that joins $x_4$ to the origin. Similarly take the tangent plane at a point $x_0'$ that approaches $x_4$ from the left remaining infinitesimally below the wire that joins $x_4$ to the origin. The maximum of these two tangent planes is the valley function $\phi_V$ that takes the form

$$\phi_V(x) = -|x_2|/4 + ax_1 + bx_2 + c.$$  

(42)

As the web is confined to the convex hull of $x_1, x_2, x_3$, the Airy stress function outside this convex hull can
be taken to be $\phi_L$ (modulo an affine function that can be set to zero without loss of generality). Convexity of the Airy stress function then implies the inequalities $\phi_L(x_i) \geq \phi_V(x_i)$ for $i = 1, 2, 3$ and $\phi_L(x_4) \leq \phi_V(x_4)$. Elementary calculations then show that these inequalities allow one no freedom in the choice of $a, b$ and $c$ and one necessarily has $a = -1/2, b = c = 0$. By convexity, the Airy stress function of any web supporting the four forces must be above

$$\phi(x) = \max\{\phi_L(x), \phi_V(x)\} = \max\{-3|x_2|/4, (1/4) - x_1, -|x_2|/4 - x_1/2\}, \quad (43)$$

and must coincide with it at the four points $x_1, \ldots, x_4$. But the polyhedral nature of $\phi(x)$ means that any other candidate convex Airy stress function must cleave it in the vicinity of $x_4$, which is forbidden. Thus (modulo the addition of an affine function) $\phi(x)$ given by (43) is the unique possibility for the Airy stress function, and the web in Figure 7(a) is the only web that can support the four forces at the four points.

**Example 4.2.** A second example of a web with completely stuck loading is shown in Figure 7(d). Forces $f_1 = [2; 0], f_2 = [-2; 2], f_3 = [-4; -6]$, and $f_4 = [4; 4]$ are applied at the points $x_1 = [0; 0], x_2 = [-1/2; 1], x_3 = [-1/2; 1]$, and $x_4 = [1; 1]$. The unique web that supports them is that drawn in Figure 7(d), and the associated Airy stress potential (modulo addition of an affine function) is

$$\phi(x) = \max\{2x_1, -2x_2 + 1, -|x_2| - (4x_1 - 1 - 3x_2)^+\}, \quad (44)$$

where $q^+ = \max\{0, q\}$. The proof proceeds similarly to the first example. The completely stuck nature of the webs in our two examples has been verified numerically.

In two dimensions when the terminal points $X$ are at the vertices of a convex polygon, the existence of an open web supporting (the assumed admissible) loading $F$ implies that such webs are never "completely stuck" with respect to the loading $F$. One may wonder: is a similar result true in three dimensions? The numerical example of Figure 8 shows, to the contrary, that there exist terminal points $X$ at the vertices of a convex polyhedron, and an admissible loading $F$ such that the associated web is "completely stuck". This example was found by starting with $N = 8$ terminal nodes at the vertices of a cube, taking an admissible loading $F$ supported at these points, then moving the terminal points backwards so that for each $j = 1, 2, \ldots, 8, x_j$ is replaced by $x'_j = x_j - \varepsilon_j f_j$, where the $\varepsilon_j \geq 0$ are increased until the loading $F$ at the terminals $X' = (x'_1, x'_2, \ldots, x'_8)$ is completely stuck, while keeping the terminals $X'$ as vertices of a convex polyhedron.

**Figure 8:** We start by applying the forces $f_i$, given in Table 1, at the 8 points shown in (a), whose coordinates are given by $x_i$ in Table 1. The points are initially chosen to be the vertices of a cube. Now, move the terminal points backwards so that for each $i = 1, 2, \ldots, 8, x_i$ is replaced by $x'_i = x_i - \varepsilon_i f_i$, where the $\varepsilon_i \geq 0$ are increased until the loadings $f_i$ at the terminals $X'$, provided in Table 1 is completely stuck, while keeping $X'$ as vertices of a convex polyhedron. The diagonal lines along the faces in figure (a) are numerical artifacts.

### 4.2.2 Unstuck loadings

The aim is to prove that, for a given loading $F$ belonging to the interior of the one of admissible loadings $A_{\mathbf{X}}$, there exists a uniloader web supporting only $F$ (up to a multiplicative constant). First, we need to prove that the cone $A_{\mathbf{X}}^*$ does not have an empty interior (Lemma 3). Then, we need to prove that if we perturb slightly the positions of the terminal points, the loading is not stuck (Lemma 3) and that there exists a connected web
Table 1: Components of the forces $f_i$ applied at the 8 points shown in Figure 8, whose coordinates in the original configuration are given by $x_i$ (Figure 8(a)), and in the final configuration by $x_i'$ (Figure 8(b)).

with all the wires under tension which supports $F$. Finally, we can prove that such a web is a uniloadable web (Theorem 4.1). To prove that the cone $A_X^*$ does not have an empty interior we need to introduce the space $R_X$ of infinitesimal rigid motions on $X = (x_1, \ldots, x_N)$ and its orthogonal $B_X$, called the space of balanced loadings on $X$, defined by

$$R_X := \{ U = (u_1, \ldots, u_N) \in (\mathbb{R}^d)^N : \exists a \in \mathbb{R}^d, \exists A \text{ antisymmetric such that } \forall i \ u_i = a + Ax_i \},$$

$$B_X := \{ F = (f_1, \ldots, f_N) \in (\mathbb{R}^d)^N : \sum_{i=1}^N f_i = 0, \sum_{i=1}^N (f_i \otimes x_i - x_i \otimes f_i) = 0 \}. \quad (45)$$

There is no loss of generality to assume that $\sum_{i=1}^N x_i = 0$ so that $X$ also belongs to $B_X$.

Recall that $A_X^*$, the cone of admissible forces $F = (f_1, \ldots, f_N)$ at the points $X = (x_1, \ldots, x_N)$, is the dual cone of $A_X := \{ U \in B_X : \forall (i, j), (u_i - u_j) \cdot (x_i - x_j) \geq 0 \}$ (see Theorem 1.1). The set $B_X$ is a subspace of $(\mathbb{R}^d)^N$ (with codimension $(d+1)/2$). The notion of interior we use is relative to this subspace.

**Lemma 3.** The cone $A_X^*$ is a subset of $B_X$ with non empty interior.

**Proof.** We have already noticed, as a consequence of Theorem 2.1 that there is no loss of generality in assuming that the points $(x_1, \ldots, x_N)$ span the space $\mathbb{R}^d$. There is no loss of generality either in assuming that it is the first points $(x_1, \ldots, x_{d+1})$ which span it.

Assume now, by contradiction, that the set $A_X^*$ has empty interior. As it is convex, this means that it is contained in a lower dimension subspace: there exists $U = (u_1, \ldots, u_N) \neq 0 \in B_X$ such that $F \cdot U = 0$ for all $F \in A_X^*$. As $(x_1, \ldots, x_{d+1})$ span $\mathbb{R}^d$, and there exists a unique affine function $u$ such that $u(x_i) = u_i$ for $1 \leq i \leq d + 1$.

Clearly, for any $(i, j) \in \{1, \ldots, N\}$, the particular loading $F^{i,j} = (f_1, \ldots, f_N)$, defined by $f_i = x_i - x_j$, $f_j = x_j - x_i$ and $f_k = 0$ whenever $k \neq i$ and $k \neq j$, belongs to $A_X^*$ (indeed a simple wire linking $x_i$ to $x_j$ is an admissible web for this particular loading). Hence $U$ satisfies $(u_i - u_j) \cdot (x_i - x_j) = 0$ for any pair $(i, j)$. This condition applied to all pairs with $i \leq d + 1$ and $j \leq d + 1$ implies that $U$ is a rigid motion. The same condition applied to all pairs $(i, j)$ with $i \leq d + 1$ and $j > d + 1$ implies that $U_j = u(x_j)$ too. Then $U$ is a non vanishing rigid motion and this contradicts the definition of $B_X$.

Let us now prove that all loadings in the interior of $A_X^*$ are unistirck. More precisely,

**Lemma 4.** Let $F$ be in the interior of $A_X^*$. Then, for $\varepsilon > 0$ small enough, $F$ also belongs to the interior of $A_{X-\varepsilon F}$.

**Proof.** We first remark that, for any $\varepsilon \in \mathbb{R}$, $F$ belongs to $B_{X-\varepsilon F}$. Indeed, for any antisymmetric matrix $A$ we have $\sum_{i=1}^N f_i \cdot (A(x_i - \varepsilon f_i)) = -\varepsilon \sum_{i=1}^N f_i \cdot (A f_i) = 0$.

Let now $U$ be any vector in $A_{X-\varepsilon F}$ with $\|U\| = 1$. For any pair $(i, j)$, it fulfills

$$(u_i - u_j) \cdot ((x_i - \varepsilon f_i) - (x_j - \varepsilon f_j)) \geq 0,$$

which implies

$$(u_i - u_j) \cdot (x_i - x_j) \geq \varepsilon (u_i - u_j) \cdot (f_i - f_j) \geq -4\varepsilon \|F\|.$$  

Let $\delta := \min_{i \neq j} |x_i - x_j|$ be the smallest distance between the points $x_i$ and $\gamma := \frac{\|F\|}{\delta}$. The vector $W := U + \varepsilon \gamma X$ satisfies

$$(w^i - w^j) \cdot (x_i - x_j) = (u_i - u_j) \cdot (x_i - x_j) + \varepsilon \gamma (x_i - x_j) \cdot (x_i - x_j) \geq 0.$$  

Therefore its projection $\overline{W}$ on $B_X$, which satisfies the same inequalities, belongs to $A_X$. 

The cone $A^*_X$ is the set of all $F$ satisfying $\forall U \in A_X, F \cdot U \geq 0$. As $F$ belongs to the interior of $A^*_X$, the function $V \to F \cdot V$ must be strictly positive on the compact intersection of $A^*_X$ with the unit sphere. Let us call $\alpha > 0$ its minimum. By homogeneity, we have for any $V$ in $A_X, F \cdot V \geq \alpha\|V\|$. When applied to $W$, this inequality gives

$$F \cdot W = F \cdot W = F \cdot U + \varepsilon \gamma F \cdot X \geq \alpha \|W\| = \alpha \|U + \varepsilon \gamma X\| \geq \alpha (1 - \varepsilon \gamma \|X\|).$$

Hence we have

$$F \cdot U \geq \alpha(1 - \varepsilon \gamma \|X\|) - \varepsilon \gamma F \cdot X \geq \alpha - \varepsilon \gamma \|X\|(\alpha + \|F\|).$$

For $\varepsilon$ smaller than $\frac{\alpha}{2\gamma(\|X\|+\|F\|)}$, we get $F \cdot U \geq \frac{\alpha}{2}\|U\|$. This inequality, valid for any $U \in A_{X - \varepsilon F}$ with $\|U\| = 1$, remains true on the whole cone $A_{X - \varepsilon F}$ by homogeneity. So the lemma is proven.

**Lemma 5.** If $F$ is in the interior of $A^*_X$ then there exists a connected web supporting $F$ at $X$ with a strictly positive stress state.

**Proof.** We first check that there exists a web $W$ supporting $F$ at $X = (x_1, \ldots, x_N)$ such that all wires with non vanishing tension make a connected set. The set $D$ of loadings $F$ for which there exists a set $I$ strictly included in $\{1, \ldots, N\}$ such that $\sum_{i \in I} f_i = 0$ is a union of subspaces (of codimension $d$) of the space $B_X$ of balanced loading. We want to avoid the case where $F$ is supported by two or more disconnected webs and clearly this may only happen if $F \in D$. In that case we use the following trick: as the interior of $D$ is empty we can find $G \in B_X$ such that $F + G$ and $F - G$ belong to $A^*_X \setminus D$. Let $W^+$ and $W^-$ be two webs supporting respectively $F + G$ and $F - G$ and let $G^+$ and $G^-$ be the associated stress measures. The measure $G_\pm := (G^+ + G^-)/2$ satisfies

$$\nabla \cdot G_\pm = \nabla \cdot G^+ / 2 + \nabla \cdot G^- / 2 + F = -(F + G)/2 - (F - G)/2 + F = 0.$$

Its support is the union of the supports of $G_+$ and $G_-$ which both are connected sets containing all the terminal nodes where the applied forces are non vanishing. Thus we get a finite connected web $W$ with a strictly positive stress state $\sigma$ that supports the loading $F = (f_1, \ldots, f_N)$ at points $X = (x_1, \ldots, x_N)$.

**Corollary 4.1.** If $F$ is in the interior of $A^*_X$ then there exists a connected web supporting $F$ at $X$ with a strictly positive stress state and only one wire joining each terminal node.

**Proof.** Lemma 4 provides an $\varepsilon > 0$ small enough for $F$ to belong to the interior of $A^*_X - \varepsilon F$. Lemma 5 then provides a connected web $W$ supporting $F$ at $X - \varepsilon F$ with a strictly positive stress state $\sigma$. Adding to $W$, for those $i \in \{1, \ldots, N\}$ such that $f_i \neq 0$, the wires $[x_i, x_i + \varepsilon f_i]$ and fixing the tension to $\|f_i\|$ in each of these wires, makes a new web supporting $F$ at $X$ with a strictly positive stress state. Clearly, as $W$ is connected, the new one is connected too.

We can finally state the theorem regarding the existence of an unloadable web for an unstuck loading.

**Theorem 4.1. Existence of unloadable webs**

For any $F$ in the interior of the admissible loading cone $A^*_X$, there exists a finite web $W$ such that $C^W_X = \{\lambda F : \lambda \geq 0\}$.

**Proof.** Corollary 4.1 states that there exists a finite connected web $W$ with a strictly positive stress state $\sigma$ that supports the loading $F = (f_1, \ldots, f_N)$ at points $X = (x_1, \ldots, x_N)$ and such that only one wire is attached to each terminal node. This web is then modified (according to Lemma 4) into a new web $W$ having the extra property that all the internal nodes have in two dimensions at most three coplanar wires meeting it, and in three dimensions at most four noncoplanar wires, or three coplanar wires, meeting it. This ensures that $W$ supports only the loadings $\lambda F$ for $\lambda \geq 0$. Indeed, as $F$ is an admissible loading for $W$ at points $X$, the unique wire attached to $x_j$ has direction $f_j$. Let $F = (f_1, \ldots, f_N)$ be another admissible loading for $W$ at $X$. Balance of forces at $x_j$ imposes $\tilde{f}_j = \lambda f_j$. As the wire attached to $x_j$ is under tension for both loadings, we have $\lambda \geq 0$. Now at each node of the web, once the (positive) tension in one of the joining wires is fixed, the balance of forces fixes the tension in all other joining wires. As the web is connected, from node to node, the tensions of all wires are fixed : $\tilde{F}$ is uniquely determined and clearly $\tilde{F} = \lambda F$.

**4.3 Possible loading cones**

Here we seek answer to the question: given a convex cone $C \subset A^*_X$ can one find a web $W$ such that $C^W_X = C$?

To proceed, as sketched in Figure 4 of [13], one approximates the convex cone $C$ by a cone, that we will denote with $C^W_X$, having a finite number $j$ of extreme rays $F^{(j)m}$, $m = 1, 2, \ldots, j$, each strictly in the interior of $C$ and hence strictly in the interior of the admissible loading cone $A^*_X$. As we are free to make arbitrary small perturbations of the extreme rays $F^{(j)m}$, we can assume that these are chosen so that at each terminal $i$, $f_i^{(j)m}$
is not collinear with $f^{(j)\ell}$ for any $m, \ell$ with $\ell \neq m$. Associated with $F^{(j)m}$ is then a uniloadable web $W^{(j)m}$ supporting, and only supporting, at the terminals $X$, the loadings $\lambda F^{(j)m}$, $\lambda \geq 0$. By adjusting the positions of the interior nodes of the different uniloadable webs $W^{(j)m}$ now indexed by $j = 1, 2, \ldots, m$ we can ensure that the webs $W^{(j)m}$ do not have overlapping interior nodes, nor overlapping collinear wires. By superimposing these uniloadable webs, for $m = 1, 2, \ldots, j$ one obtains the web $W_j$ having the desired loading cone. It may happen that some wire pairs cross when we superimpose the webs, generating an additional interior node at the crossing point. This is still okay, as balance of forces at the crossing point ensures that the tension in the wire remains the same on opposite sides of the crossing point. If more than two wires cross at the same point, then we can perturb the uniloadable webs to avoid this.

Taking the limit $j \to \infty$ allows us to approximate $C$ arbitrarily closely, so that $C^{W_j} \to C$.

5 Conclusions

In this paper we provide full answer to the question as to whether, given a set of forces applied to specific points, called terminal points, there exists a web that supports such forces with all the wires under tension. Specifically, we provide a necessary and sufficient condition on the loading forces which guarantees the existence of such a web, see Theorem 1.1. Such a condition corresponds to a finite dimensional linear programming problem: if this has solution, then a web exists which is formed by the wires connecting pairwise the terminal points. Conversely, any web under tension supporting the given loading can be replaced by the web provided by the linear programming problem.

The conditions related to the linear programming problem are inequalities expressed in terms of the displacements of the terminal points: they form a cone in the displacement space and the edges of the cone correspond to those displacements that satisfy the conditions as equalities. In case the terminal points form the vertices of a convex polygon, these extreme edges correspond precisely (up to an infinitesimal rigid body motion) to clam-shell movements and do not include any other movements. By clam-shell movements we denote a displacement field that arises when one breaks the convex polygon connecting the terminal points into two non-overlapping subpolygons connected at one vertex and fixes one subpolygon and infinitesimally rotates the other one, so the clam opens slightly. In the case there is at least one terminal point that lies inside the convex hull of the terminal points, the extreme rays of the cone of admissible displacements correspond to types of displacements that are not simply clam-shell movements.

In practical situations one would like to have uniloadable webs, that is webs that support only one loading and all positive multiples of it: such webs allow one to channel stresses in desired ways and the superposition of them allows one to get a desired convex loading cone. To construct a uniloadable web in two-dimensions, one has to replace each closed minimal loop, that is any polygon formed by the intersection of wires that cannot be divided into subpolygons, by an open web (not containing any closed loop). This is always possible if the terminal points are positioned at the vertices of a convex polygon. If that is not the case, then there will still be minimal closed loops in a number equal to that of the terminal points which lie inside the convex hull of the terminal points.

In general, to construct uniloadable webs, one has to reduce the number of wires meeting at either a terminal point or at an internal node. The first step is to modify the web so that only one wire is attached to each terminal point. We proved that this is possible only when the given loading lies inside the cone formed by the inequality conditions associated with the dual linear programming problem. If, instead, the loading corresponds to one of the extreme rays of such a cone, then we have that for some webs this modification is impossible and we say that such webs have stuck loadings. We provided two examples of webs of this type in two dimensions, see Examples 4.1 and 4.2. Since in two dimensions we know that a web with terminal points that are vertices of a convex polygon can always be replaced by an open web, we have that such webs are never completely stuck: indeed, in both Example 4.1 and 4.2 the terminal points are not vertices of a convex polygon. This does not hold in the three-dimensional case for which one can find a web with stuck loadings which have the terminal points forming a convex polyhedron (see Figure 8). On the other hand, if the loading belongs to the interior of the cone formed by the loadings in the dual linear programming problem, then we provide a general procedure to reduce the number of wires meeting at each internal node where initially 5 or more wires meet.
