Abstract

Aims. We present the analysis of 26 nights of V and I time-series observations from 2011 and 2012 of the globular cluster M 30 (NGC 7099). We used our data to search for variable stars in this cluster and refine the periods of known variables; we then used our variable star light curves to derive values for the cluster’s parameters.

Methods. We used difference image analysis to reduce our data to obtain high-precision light curves of variable stars. We then estimated the cluster parameters by performing a Fourier decomposition of the light curves of RR Lyrae stars for which a good period estimate was possible. We also derive an estimate for the age of the cluster by fitting theoretical isochrones to our colour-magnitude diagram (CMD).

Results. Out of 13 stars previously catalogued as variables, we find that only 4 are bona fide variables. We detect two new RR Lyrae variables, and confirm two additional RR Lyrae candidates from the literature. We also detect four other new variables, including an eclipsing blue straggler system, and an SX Phoenicis star. This amounts to a total number of confirmed variable stars in M 30 of 12. We find Fourier decomposition of the light curves of the RR Lyrae stars to derive cluster parameters using empirical relations. We find a cluster metallicity [Fe/H]UVES = −2.11 ± 0.06 kpc, and a distance of 8.32 ± 0.20 kpc (using RR0 variables), 8.10 kpc (using one RR1 variable), and 8.35 ± 0.42 kpc (using our SX Phoenicis star detection in M 30). Fitting isochrones to the CMD, we estimate an age of 13.0 ± 1.0 Gyr for M 30.

Key words. globular clusters – RR Lyrae – variable stars

1. Introduction

In this paper we analyse time-series observations of M 30 (NGC 7099, or C2137-234 in the IAU nomenclature; \( \alpha = 21\text{h}40\text{m}22\text{s}, \delta = -23\text{d}10\text{m}47.5\text{s} \) at J2000.0), one of the most metal-poor globular clusters known, with \([\text{Fe/H}\] \approx -2.1\), located at a distance of \( \sim 8 \) kpc. This cluster is thought to be of extra-Galactic origin, due to its retrograde orbit (Allen et al. 2006), pointing to its possible accretion by the Milky Way following an encounter with a satellite, as well as its position on the age-metallicity diagram.

* The full light curves presented in this paper (Table 2) are only available in electronic form at the Centre de données astronomiques de Strasbourg (CDS) via anonymous ftp to cdsarc.u-strasbg.fr (130.79.128.5) or via http://cdsweb.u-strasbg.fr/cgi-bin/qcat?J/A+A/

(Forbes & Bridges (2010). M 30 is also thought to have undergone core collapse (e.g. Djorgovski & King (1986)). Here we detect and classify already reported, as well as new variables, and use Fourier decomposition to derive properties of the RR Lyrae stars in this cluster. We then estimate the cluster parameters of M 30, providing us with an independent estimate of the metallicity, distance and age of this cluster, and the first using this method.

Our observations are detailed in Sec. 2; we discuss the variables in M 30 in Sec. 3, and in Sec. 4 we derive properties of the RR Lyrae stars in this cluster using Fourier decomposition and empirical relations. We use this to derive properties of the cluster in Sec. 5 and summarise our findings.

2. Observations and reductions

2.1. Observations

We obtained Johnson $V$- and $I$-band data with the Danish Faint Object Spectrograph and Camera (DFOSC) imaging camera at the Danish 1.54m telescope at La Silla in Chile, as part of a programme with the MiNDSTEp consortium. In this programme we are making use of parts of the night as part of a programme with the MiNDSTEp consortium.

Faint Object Spectrograph and Camera (DFOSC) imaging observations are evenly split between $V$ and $I$ bands. Our reference image consists of 5 stacked images, with a combined exposure time of 100 s, and a FWHM of 3.88 pixels ($\sim$1.2$''$), also taking care to avoid including images with many saturated stars. Our reference image consists of 5 stacked images, with a combined exposure time of 100 s, and a FWHM of the point-spread function (PSF) of 3.88 pixels ($\sim$1.2$''$) in $V$, while in $I$ the combined exposure time is 80 s from 4 images, and the PSF FWHM is 3.31 pixels ($\sim$1.3$''$). For each filter, the source positions and reference fluxes were then extracted from the reference image. Images were then registered with the reference, and the reference was convolved with the kernel solution and subtracted from each image, producing a set of difference images. Finally, difference fluxes were measured from each difference image for each source, which we used to construct a set of light curves. In Table 1 we outline the format of the data as it is provided in electronic format with the online version of this paper.

As was noted in previous papers, blending due to the presence of other objects near a source may lead to the reference flux being overestimated. However, non-variable sources are still fully subtracted in the difference images, while variable objects have the amplitude of their variability underestimated if their reference flux is affected by blending, although the shape of their light curve, crucially, will remain unaffected.

2.2. Difference image analysis

As in our previous studies of variables in globular clusters (Figueras et al. 2013; Kains et al. 2013; Arellano Ferro et al. 2011), we used the DanIDL pipeline (Bramich et al. 2013; Bramich 2008) to reduce our observations. Using difference image analysis (DIA) enabled us to obtain high-precision photometry for sources within our field of view. The reader is referred to our previous papers (e.g. Bramich et al. 2011) for a detailed description of the software used; we provide a short summary of the main steps here.

After preprocessing (bias level correction and flattening), our images were blurred with a Gaussian of full-width half-maximum (FWHM) of 3 pixels to avoid undersampling, which is detrimental for determining the kernel in DIA. We then produce a reference image for each filter, stacking images within 10% of the best seeing ($\sim$1.2$''$), also taking care to avoid including images with many saturated stars. Our reference image consists of 5 stacked images, with a combined exposure time of 100 s, and a FWHM of the point-spread function (PSF) of 3.88 pixels ($\sim$1.2$''$) in $V$, while in $I$ the combined exposure time is 80 s from 4 images, and the PSF FWHM is 3.31 pixels ($\sim$1.3$''$). For each filter, the source positions and reference fluxes were then extracted from the reference image. Images were then registered with the reference, and the reference was convolved with the kernel solution and subtracted from each image, producing a set of difference images. Finally, difference fluxes were measured from each difference image for each source, which we used to construct a set of light curves. In Table 1 we outline the format of the data as it is provided in electronic format with the online version of this paper.

As was noted in previous papers, blending due to the presence of other objects near a source may lead to the reference flux being overestimated. However, non-variable sources are still fully subtracted in the difference images, while variable objects have the amplitude of their variability underestimated if their reference flux is affected by blending, although the shape of their light curve, crucially, will remain unaffected.

2.3. Photometric calibration

2.3.1. Self-calibration

Although all photometry is affected by systematic errors, steps can be taken to correct for this, in particular with time-series photometry, for which we can carry out a self-calibration of the data (e.g. Padmanabhan et al. 2008). To do this, we use the method of Bramich & Freudling (2012) to derive magnitude offsets to be applied to each photometric measurement. In practice, this equates to correcting for errors in the fitted value of the photometric scale factor $p$. We find magnitude offsets of the order of 2-3 mmag for most data points, which leads to small difference in the resulting light curves.

2.3.2. Photometric standards

We converted the instrumental magnitudes from our data reduction pipeline to standard Johnson-Kron-Cousins magnitudes by carrying out a linear fit to the relation between our light curve magnitudes and those of the photometric standards of Stetson (2000) in the field of this cluster. The relations, shown in Fig. 1 were used to obtain light curves in standard magnitudes. The standard stars we used cover the full range of colour and magnitude spanned by our CMD. No significant colour term was found and the correlation coefficients are $\sim$ 1 for both filters.

2.4. Astrometry

We used GAIA to perform the astrometry by matching $\sim$400 manually picked stars from our reference images with
Table 2. Format for the time-series photometry of all confirmed variables in our field of view. The standard $M_{\text{std}}$ and instrumental $m_{\text{ins}}$ magnitudes listed in columns 4 and 5 respectively correspond to the variable star, filter and epoch of mid-exposure listed in columns 1-3, respectively. The uncertainty on $m_{\text{ins}}$ is listed in column 6, which also corresponds to the uncertainty on $M_{\text{std}}$. For completeness, we also list the reference flux $f_{\text{ref}}$ and the differential flux $f_{\text{diff}}$ (columns 7 and 9 respectively), along with their uncertainties (columns 8 and 10), as well as the photometric scale factor $p$. Definitions of these quantities can be found in e.g. Bramich et al. (2011), Eq. 2-3. This is a representative extract from the full table, which is available with the electronic version of the article.

Table 3. Equatorial celestial coordinates of confirmed variables in M 30 at the epoch of the reference image, HJD~2456151.84.

3. Variables in M 30

The first three variables (V1-3) in this cluster were detected by Bailey (1902) using photographic observations made at the Harvard College Station in Arequipa, Peru. V4 was then reported by Rosino (1949), who discovered it using observations of M 30 at 175 epochs, taken between 1946 and 1948 with the 60cm reflecting telescope at the Lojano Astronomical Station, near Bologna in Italy. Rosino also derived periods for V1-3, and refined his period for V1 in a later paper (Rosino 1961). He also noted that V4 did not present the characteristics of an RR Lyrae type variable. He described it as an unusual object, reaching a magnitude of 16.4, remaining at that level for several days, before dropping below the limits of detectability of his photographic plates, i.e. below $\sim$18th magnitude. Other light curve features led him to conclude that V4 is a variable of type U Geminorum. This was confirmed in several subsequent publications by Margon & Downes (1983), who obtained spectroscopic evidence that V4 is a cataclysmic variable, and Machin et al. (1991), who also concluded that V4 is most likely a foreground object rather than a cluster member. Pietrukowicz et al. (2008) found a relatively high V-band brightness consistent with that assessment, and also noted that V4 has a likely X-ray counterpart detected by the ROSAT satellite.

Finally, V5-12 were all reported as variable by Terzan (1968), and V13 was reported by Terzan & Rutily (1973),
Based on photographic observations taken at the 1.52m telescope at ESO between 1972 and 1974; however they did not publish light curves or periods for any of those variables. Pietrukowicz & Kaluzny (2004) analysed HST archival data of M 30 and identified two previously unknown RR Lyrae variables, as well as four W UMa-type contact binaries, and an eclipsing close-binary variable with ellipsoidal variations. However, they did not assign those variables catalogue V numbers.

This amounts to a total of 13 catalogued variables in the cluster, although V4 is now thought to be a foreground object. There are also 7 additional variables reported by Pietrukowicz & Kaluzny (2004), including 2 new RR Lyrae. The present study of M 30 is the first from the Southern hemisphere using CCD photometry, allowing us to carry out a significant update of the variable star population in this cluster.

### 3.1. Stars that do not show variability

We find that all of the stars V5-V13, reported by Terzan (1968) and Terzan & Rutilla (1973) as variables, do not show signs of variability in our data, to within the limits of the rms scatter in our light curves; those limits are given in Table 4. We are also unable to detect variability of the five contact binaries listed by Pietrukowicz & Kaluzny (2004), for most of these, we attribute this to the fact that the variations have amplitudes of ∼0.3 mag, for objects with V ∼ 20 mag, which is very challenging to detect within the rms of our data (Fig. 2). This is especially difficult in the crowded central core, where blending leads to photon noise dominating any intrinsic variability signal. This is also true for the two brightest eclipsing variables, which have V magnitudes of ∼17.3 and ∼17.9 and variation amplitudes of ∼0.3 mag. The advent of electron-multiplying CCD (EMCCD) cameras, coupled with DIA, will allow us in the future to obtain high-quality photometry even for stars in the crowded cores of clusters (Skottfelt et al. 2013), and to verify the variability status of these objects using ground-based photometry.

### 3.2. Detection of known variables

We recover the first three known RR Lyrae in this cluster (V1-V3) in our data, and calculate periods for each of them, using phase dispersion minimisation (PDM: Stellingwerf 1978) and the “string length” method (Lailer & Kinman 1965). In order to use the longest possible baseline to derive precise periods for these three variables, we used the data from Rosino (1949); these data are published in a table in that paper, and we provide them as an additional resource with the electronic version of this paper. We also used these data to refine our periods by optimising the alignment in phase of that data set with ours; this is highly sensitive to the period, thanks to the baseline of ∼63 years. We also recovered the two additional RR Lyrae stars reported by Pietrukowicz & Kaluzny (2004) and assign them catalogue numbers V15 and V19, and calculated refined periods for these two stars. We note that V19 is highly blended due to its location in the very centre of the cluster, which explains its peculiar position on the CMD.

We also detect the U Gem variable V4, including some data taken during an outburst period. This star is discussed in more detail in Sec. 3.3.

### 3.3. Detection of new variables

As in our previous studies, we searched for new variables using three methods. Firstly, we constructed a stacked image S consisting of the sum of the absolute values of the deviations $D$ of each image from the convolved reference image, divided by the pixel uncertainty $\sigma$, so that

$$S_{ij} = \sum_{k} \frac{|D_{kij}|}{\sigma_{kij}}. \quad (1)$$

Stars that deviate consistently from the reference image then stand out in this stacked image. Using this method, we discovered 2 new RR Lyrae stars, V14 and V16, both of RR1 type, with V16 also showing signs of amplitude and period modulation due to Blazhko effects or non-radial pulsation (see Sec. 3.3). Secondly, we inspected the light curves of objects which stand out on a plot of root mean square magnitude deviation versus mean magnitude, shown in Fig. 4.

Finally, we also searched for variables by conducting a period search for all our light curves using the string length method, and computing the ratio $S_{R}$ of the string length for the best- to that of the worst-fit periods, with the smallest ratios expected for true periodic variations. We inspected visually all of the light curves of stars with $S_{R} < 0.55$, where the threshold value of 0.55 was chosen by inspecting the distribution of $S_{R}$ (see Fig. 3). Using this method, we discovered V17, V18, V20 and V21.

All confirmed variables are listed in Table 4, in which we also give epochs, periods and amplitudes. The corresponding light curves are shown in Figs. 4 and 5. A finding chart of the cluster with the location of the confirmed variables is shown in Fig. 6 and a CMD showing the locations of all confirmed variables is shown in Fig. 7.

| #  | $<V>$  | rms ($V$) | $<I>$  | rms ($I$) |
|----|--------|----------|--------|----------|
| V5 | 17.42  | 0.035    | 16.75  | 0.047    |
| V6 | 15.34  | 0.013    | 15.13  | 0.037    |
| V7 | 16.63  | 0.021    | 15.84  | 0.018    |
| V8 | 15.60  | 0.010    | 14.31  | 0.011    |
| V9 | 15.40  | 0.012    | 15.08  | 0.021    |
| V10| 15.44  | 0.010    | 15.22  | 0.017    |
| V11| 16.11  | 0.013    | 15.25  | 0.012    |
| V12| 15.49  | 0.011    | 15.38  | 0.015    |
| V13| 15.09  | 0.040    | 14.78  | 0.030    |

Table 4. Mean magnitudes and rms limits for the stars previously catalogued as variable, but for which we do not find variability.
Table 5. Epochs, periods, mean magnitudes and amplitudes $A$ in $V$ and $I$ for all confirmed variable stars in M 30.

For RR Lyrae stars, $< V >$ and $< I >$ are intensity-weighted mean magnitudes, while for the other variables, they are inverse-variance-weighted mean magnitudes. *Rosino (1961) revised the period of V1 to 0.743608 d. +The period given for V4 is that of the sinusoidal variations seen during the quiescent part of the light curve, and the mean magnitudes are also those during quiescent phase; outburst mean magnitudes are given in the text (see Sec. 3.4). For V19, the mean magnitudes are overestimated and amplitudes are underestimated due to blending, as discussed in the text.

3.4. Discussion of individual variables

We are unable to determine the nature of V17 with certainty. The combination of its position on the red giant branch and a short period of $\sim 0.06d$ makes it difficult to classify, although the shape of the light curve and the period would both be consistent with an SX Phoenicis variable blended with a red giant star (e.g. Darragh & Murphy 2012). This is difficult to quantify, and higher-resolution data would be needed to investigate that possibility. From the position of V18 on the CMD and its light curve showing minima of different depths, we suggest that it is an eclipsing blue straggler binary system, of which only 6 examples are known in globular clusters (Kai & Sheng-Bang 2012). We classify V20 as an SX Phoenicis variable, from its light curve, period, and position on the CMD; we only identify one pulsation period for this variable. We could not reach any conclusion as to the nature of V21, because of the quality of its light curve; however variability is clear from both the $V-$ and $I-$band light curves, when discarding the poor-quality 2011 data, and data with large error bars, from the $I$ light curve. However we do verify that the variability of V21 is genuine in the difference images, and it is isolated, so there is no reason to believe that the variability is due to contamination from other variables. Below we discuss some of the variables in more detail.

3.4.1. V2

Figs. 4 and 5 show that our best period for V2 leads to an unsatisfactory phased light curve in both $V$ and $I$. We suggest that the disjointed light curve may be due to a Blazhko effect (Blazhko 1907) in this object; more observations are needed to confirm this.

3.4.2. V3

Like V2, but to a lesser extent, the light curves V3 seem disjointed, which we suggest may be due to a Blazhko effect. However, and more observations are needed to investigate this further.

3.4.3. V4

For the U Geminorum variable V4, we measured a quiet $V$-band median magnitude of 20.21 $\pm$ 0.48 mag, while during outburst, we find a median magnitude of 17.44 $\pm$ 0.04 mag, giving an amplitude of 2.74 mag; in the $I$ band we find median values of 19.05 $\pm$ 0.40 (quiet) and 16.84 $\pm$ 0.48 (outburst), and an amplitude of 1.91 mag. Machin et al. (1991) found V4 to be significantly brighter, with $< V >_{\text{quiet}}$ $\sim$ 18.7 mag, and Pietrukowicz et al. (2008) also found $< V >_{\text{quiet}}$ $\sim$ 19 mag. It is interesting to note that, while our $V$ data only covers one outburst, the $I$ data covers three outburst, which show large variations in magnitude, by as much as $\sim$ 1 mag between different outbursts.

We also conducted a period search for the quiet part of the light curve; Machin et al. (1991) used the quiescent $B-V$ colour they find from their spectra of this object, and the relations of Echevarria & Jones (1984) between $B-V$ and $P$ for dwarf novae, to conclude that the orbital period of V4 must be $\sim 5$ hours. We find a period during quiescence of $P = 0.0923$ days, or $P \sim 2.22$ hours, in agreement with that conclusion. In Fig. 8 we show the phased quiescent light curves with this period, while the unphased light curve is shown in Fig. 9.

3.4.4. V16

The light curves in both $V$ and $I$ suggest that our single best period does not lead to a satisfactory phased light curve; we discuss possible explanations for this here. First we considered the possibility that V16 might be a double-mode RR Lyrae (RR01) star, which have only been detected in a few Galactic globular clusters (e.g. Nemec 1985, Clement et al. 1993, Clementini et al. 2004, and references therein). To investigate this, a search for the fundamental and first-overtone pulsation periods was conducted using the string-length method. We start by conducting a period search to identify a first period; for this we find $P = 0.3254$. Assuming this to be the first-overtone period, and assuming an overtone-to-fundamental period ratio similar to what was found for double-mode RR Lyrae stars in M15, $P_1/P_0 \sim 0.748$ (Cox et al. 1983), we expect a funda-
Figure 4. Phased V-band light curves of the variables with a period estimate. Different colours are used for different nights, with the colour coding given in the form of a colour bar spanning the whole time range of the observations (top panel). Fourier decomposition fits are overplotted for the objects for which those were successful.

mental period around \( P_0 \sim 0.435 \). We pre-whiten our data for the first-overtone period to check whether we can recover this period. In the V data, we find no evidence for such a period or any other pulsation period in our resulting power spectrum. We find similar results using the I data, leading us to conclude that the unsatisfactory phasing of the V16 light curves is not due to double-mode pulsation.

Secondly, we also tried to fit the light curve by including a secular period change. To do this, we minimise the string length, but with a time-dependent period \( P(t) \) and phase \( \phi(t) \),

\[
P(t) = P_0 + \beta(t - E) \tag{2}
\]
\[
\phi(t) = (t - E)/P(t) - \lfloor (t - E)/P(t) \rfloor \tag{3}
\]

where \( \beta \) is the rate of change of the period and \( P_0 \) is the period at epoch \( E \). We varied \( P_0 \) within a small range near the value we found using the string-length method, and for
Figure 5. Same as Fig. 4 but for the $I$ band. For V21, we only plot data points with error $\sigma < 0.3$ mag and do not plot 2011 data due to poor photometry.

Each value of $P_0$ we explored a grid of values for $\beta$ ranging between $-10^{-7}$ and $10^{-7}$ d day$^{-1}$. From this we found that no such secular period change can explain the scatter in our phased light curve of V16.

This leads us to conclude that V16 either exhibits the Blazhko effect, or shows signs of non-radial pulsation. Amplitude variations are clear when comparing the 2011 (black filled circles on Fig. 4 and 5) and 2012 data, and Blazhko-like effects cause period modulations as well, which would explain that the light curve is not phased properly when using a single best-fit period. On the other hand, the scatter in the light curves, particularly in the $I$-band, is very similar to that observed in light curves of some of the variables in M 55 detected by Olech et al. (1999). They concluded that the scatter in the variations were caused by non-radial oscillations, and we suggest here that non-radial pulsation could also be the source of the scatter in the light curves of V16.
Figure 6. Finding chart for the confirmed variable objects in M 30, using our $V$ reference image. North is up and East is to the right. The image size is $11.57 \times 4.55$ arcmin$^2$, while each stamp size is $23.4 \times 23.4$ arcsec$^2$. White circles and labels indicate the locations of the variables, and each of the variables we detect in our data is shown with a crosshair at the centre of an individual stamp. Note that the display scale of each stamp is different in order to make the source visible.

4. Fourier decomposition of RR Lyrae star light curves

Applying Fourier decomposition to the $V$-band light curves of RR Lyrae variables with sufficient phase coverage allows us to derive several of their properties, which we then use as a proxy for the parameters of their host cluster. Fourier decomposition consists in fitting light curves with the Fourier series

$$m(t) = A_0 + \sum_{k=1}^{N} A_k \cos \left[ \frac{2\pi k}{P} (t - E) + \phi_k \right],$$

where $m(t)$ is the magnitude at time $t$, $N$ is the number of harmonics used in the fit, $P$ is the period of the variable, $E$ is the epoch, and $A_k$ and $\phi_k$ are the amplitude and phase of the $k^{th}$ harmonic. The Fourier parameters, which are epoch-independent, are then defined as

$$R_{ij} = \frac{A_i}{A_j}$$

$$\phi_{ij} = j\phi_i - i\phi_j.$$
we also adopt $D_m < 5$ as a selection criterion to estimate stellar properties.

Although some acceptable fits could be obtained for V2, with $D_m < 5$, we exclude it from the analysis as well because we suspect its light curve might be affected by Blazhko effects. Furthermore, the value of the physical parameters is very sensitive to the number of harmonics used in the fit. Although we suggested in Sec. 3.4 that V3 might also be affected by Blazhko effects, we find that the Fourier fits and resulting physical parameters are stable for V3, and therefore include it in the following analysis. We note, however, that this may account for the larger value of $D_m$ we find for V3. We also exclude V19 because our phase coverage does not enable us to find a good Fourier fit. This leaves us with 4 RR Lyrae stars with good Fourier decompositions, three RR0 (V1, V3 and V15) and one RR1 (V14).

4.1. Metallicity

We use the empirical relations ofJurcsik & Kovács (1996) to derive the metallicity [Fe/H] for each of the variables for which we could obtain a successful Fourier decomposition. The relation is derived from the spectroscopic metallicity measurement of field RR0 variables, and it relates [Fe/H] to the period $P$ and the Fourier parameter $\phi_{s31}$, where $s$ denotes a parameter obtained by fitting a sine series rather than the cosine series we fit with Eq. (4). [Fe/H] is then expressed as

$$[\text{Fe/H}]_J = -5.038 - 5.394 P + 1.345 \phi_{s31}$$

where the subscript J denotes a non-calibrated metallicity, the period $P$ is in days, and $\phi_{s31}$ can be calculated via

$$\phi_{ij} = \phi_{ij} - (i - j) \frac{\pi}{2}.$$ (8)

We transform these to the metallicity scale ofZinn & West (1984) (hereafter ZW) using the relation fromJurcsik (1995):

\begin{figure}[h]
\centering
\includegraphics[width=\textwidth]{figure7.png}
\caption{(V − I), V colour-magnitude diagram from our photometry. The location of RR Lyrae (filled circles, RR0 in red, RR1 in green), SX Phoenicis (green triangles), U Geminorum (Blue square), eclipsing blue straggler (black open square) and other variables of uncertain type (green filled squares) are shown. On the right of the plot, typical error bars are plotted for different magnitude levels. Also plotted are isochrones from VandenBerg & Clem (2003) for ages of 9, 10.5, 12, 13.0 (our best-fit isochrone), 13.5 and 15 Gyr.}
\end{figure}
Table 6. Parameters from the Fourier decomposition. A good decomposition could not be obtained for V19, due to poor phase coverage; the Fourier fit to V2 was also poor, and V16 is excluded because it shows signs of amplitude and period modulation due to Blazhko effects or non-radial pulsation. Numbers in parentheses are the 1-σ uncertainties on the last decimal place.

Table 7. Physical parameters for the RR Lyrae variables calculated using the Fourier decomposition parameters and the relations given in the text. Numbers in parentheses are the 1-σ uncertainties on the last decimal place.

Figure 2. Plot of root mean square magnitude deviation versus mean magnitude for all stars for which photometry was obtained. Plots are for the V-band (top) and I-band (bottom). Classified variables are marked as filled circles, with RR Lyrae in red, SX Phoenicis and blue stragglers in light green, U Geminorum in blue, and variables of unknown type as dark green triangles. Non-variable objects previously cataloged as variable in the literature are marked with red crosses.

Figure 3. Plot of the distribution of the $S_R$ statistic as defined in the text, for our V-band light curves.

Figure 4. Plot of the distribution of the $S_R$ statistic as defined in the text, for our V-band light curves.

Figure 5. Plot of the distribution of the $S_R$ statistic as defined in the text, for our V-band light curves.

\begin{align}
[\text{Fe/H}]_{ZW} &= \frac{[\text{Fe/H}]_{J} - 0.88}{1.43}.
\end{align}

\begin{align}
[\text{Fe/H}]_{ZW} &= 2.424 - 30.075P + 52.466P^2 \\nonumber \\
&+0.982\phi_{31} + 0.131\phi_{31}^2 - 4.198\phi_{31}P
\end{align}

Metallcity values calculated using Eq. (7) & (9) and (10) are given in Table 7.
Effective Temperature

The Fourier parameters can also be used to calculate the effective temperature, using empirical relations derived by Jurcsik (1998). Those relations link the \((V - K)_0\) colour to \(P\) as well as several of the Fourier coefficients and parameters:

\[
(V - K)_0 = 1.585 + 1.257P - 0.273A_3 - 0.234\phi^s_{31} \tag{11}
\]
\[
\log T_{\text{eff}} = 3.9291 - 0.1112(V - K)_0 - 0.0032[\text{Fe/H}] \tag{12}
\]

For RR1 variables, Simon & Clement (1993) used theoretical models to derive an empirical relation,

\[
\log T_{\text{eff}} = 3.7746 - 0.1452\log P + 0.0056\phi^s_{31} \tag{13}
\]

We list the temperatures we derived for each RR Lyrae star in Table 7. As noted in our previous analyses, there are several caveats to deriving temperatures with Eq. (12) and (13). These relations yield values of \(T_{\text{eff}}\) for RR0 and RR1 stars on different absolute scales. Furthermore, the effective temperatures we derive here show systematic deviations from the relations predicted by evolutionary models of Castelli (1999) or the temperature scales of Sekiguchi & Fukugita (2000). Bearing these caveats in mind, we use these relations to derive temperature estimates in order to be consistent with our previous studies.

Absolute Magnitude

Kovács & Walker (2001) derived empirical relations to calculate V-band absolute magnitudes for the RR0 variables, linking the magnitude to Fourier coefficients through

\[
\log m_V = 3.7746 - 0.1452\log P + 0.0056\phi^s_{31} \tag{13}
\]

We list the magnitudes we derived for each RR Lyrae star in Table 7. As noted in our previous analyses, there are several caveats to deriving magnitudes with Eq. (13). These relations yield values of \(m_V\) for RR0 and RR1 stars on different absolute scales. Furthermore, the effective temperatures we derive here show systematic deviations from the relations predicted by evolutionary models of Castelli (1999) or the temperature scales of Sekiguchi & Fukugita (2000). Bearing these caveats in mind, we use these relations to derive magnitude estimates in order to be consistent with our previous studies.

Figure 8. Phased quiescent light curves of V4 in the \(V\)–(top) and \(I\)-band (bottom). Colour coding is the same as for Fig. 4. For clarity we only plot data points with errors \(\sigma < 0.3\) mag.

Figure 9. 2012 \(V\)– and \(I\)–band light curves of V4. \(V\) data is plotted in black, and \(I\) data in red. For clarity we plot only data points with errors \(\sigma < 0.3\) mag. The \(x\)–axes are given in HJD-2450000.
\[
M_V = -1.876 \log P - 1.158 A_1 + 0.821 A_3 + K_0, \tag{14}
\]
where \(K_0\) is a constant. As in our previous studies, we adopt a value of \(K_0 = 0.41\) mag to be consistent with a true LMC distance modulus of \(\mu_0 = 18.5\) mag \cite{Freedman04}. For RR1 variables, we use the relation of \cite{Kovacs98},
\[
M_V = -0.961 P - 0.044 \phi_{21}^c - 4.447 A_4 + K_1, \tag{15}
\]
where \(K_1\) is a constant, for which we choose a value of 1.061 with the same justification as for our choice of \(K_0\).

We also converted the magnitudes we obtained to luminosities using
\[
\log \left( \frac{L}{L_\odot} \right) = -0.4 \left[ M_V + B_C(T_{\text{eff}}) - M_{\text{bol},\odot} \right], \tag{16}
\]
where \(M_{\text{bol},\odot}\) is the bolometric magnitude of the Sun, \(M_{\text{bol},\odot} = 4.75\), and \(B_C(T_{\text{eff}})\) is a bolometric correction which we determine by interpolating from the values of \cite{Montegriffo98} for metal-poor stars, and using the value of \(T_{\text{eff}}\) we derived in the previous section. Values of \(M_V\) and \(\log \left( \frac{L}{L_\odot} \right)\) for the RR0 and RR1 variables are listed in Table 7. Using our average values of \(M_V\), in conjunction with the average values of \([\text{Fe/H}]_{\text{ZW}}\) (Sec. 4.1), we find a good agreement with the \(M_V - [\text{Fe/H}]_{\text{ZW}}\) relation derived in the literature \cite[e.g.][see Fig. 9 of that paper]{Kains12}.

5. Cluster properties

5.1. Oosterhoff Type

We find mean periods \(< P_{\text{RR0}} > = 0.693 \pm 0.038\) d and \(< P_{\text{RR1}} > = 0.346 \pm 0.003\) d, with a proportion of 43\% of the RR Lyrae in this cluster being of RR1 type.

From these values of \(< P_{\text{RR0}} >\) and the fraction of RR1 stars in M 30, as well as its low metallicity, we confirm previous classification of this cluster in the literature as Oosterhoff type II \cite[e.g.][see Fig. 10]{Lee99}. This is also confirmed by comparing the locations of our variables on a Bailey diagram \cite{Cacciari03} to the tracks derived by \cite{Cacciari03} for evolved stars.

5.2. Distance

5.2.1. Using the RR Lyrae stars

We can use the \(A_0\) parameter from our Fourier decompositions, which corresponds to the mean apparent V magnitudes of the RR Lyrae, as well as the absolute magnitudes of the RR Lyrae we derived in Sec. 4.3 to derive the distance modulus to M 30. The mean value of the \(A_0\) for our RR0 variables is 15.09 \pm 0.03 mag, while the mean of the absolute magnitudes is 0.40 \pm 0.04 mag. This yields a distance modulus of \(\mu = 14.69 \pm 0.05\) mag. Using the parameters for our RR1 variable (V14, see Tables 6 & 7), we find \(\mu = 14.64\) mag.

The reddening towards this cluster has been estimated in the literature by several authors, with values of \(E(B-V)\) ranging from 0.01 to 0.12 mag. \cite{Zinn82} derived a value of \(E(B-V) = 0.01\) mag from integrated light measurements. \cite{Bolt82} adopted a value of \(E(B-V) = 0.02\) mag, while \cite{Richer88} found a value of \(E(B-V) = 0.068 \pm 0.035\) mag. \cite{Piotto99} derived \(E(B-V) = 0.05\) mag from their CMD analysis, and \cite{Samus97} found values of \(E(B-V) = 0.09\) or 0.12 mag, depending on the metallicity of the isochrone they fitted to their CMD. \cite{Ferraro99} report a value for this cluster \(E(B-V) = 0.03\) mag.

Here we adopt a value of \(E(B-V) = 0.03 \pm 0.01\) mag, as well as a value of \(R_V = 3.1\) for our Galaxy. We use these to derive mean true distance moduli of \(\mu_0 = 14.60 \pm 0.05\) mag.
magnitudes and $\mu_0 = 14.54$ mag, from our RR0 and RR1 variables respectively. These values correspond to mean physical distances of $8.32 \pm 0.20$ kpc and 8.10 kpc. Since the distance values are sensitive to our chosen value of $E(B-V)$, we also derive distances using the largest value of reddening in the literature $E(B-V) = 0.12$ mag, to find a lower limit for the distances of $7.32 \pm 0.17$ and 7.13 kpc. Our values for the distance to the cluster are consistent with previous estimates in the literature, reported in Table 5.

5.2.2. Using SX Phoenicis stars

SX Phoenicis stars can be used as standard candles thanks to their period-luminosity ($P - L$) relation (e.g. [Jeon et al. 2003]), allowing us to estimate the distance to M 30 using the detected SX Phoenicis star in our sample, V20. We use the $P - L$ relation of [Cohen & Sarajedini 2012],

$$M_V = -(1.640 \pm 0.110) - (3.389 \pm 0.090) \log P_f,$$

where $P_f$ denotes the fundamental-mode pulsation period. Using $P_f = 0.040199$ d for V20, we find $M_V = 3.09 \pm 0.11$ mag. Using a mean magnitude of $< V >= 17.79$ mag, $E(B-V) = 0.03$ mag, this yields a distance modulus of $14.61 \pm 0.11$ mag, which corresponds to a physical distance of $8.35 \pm 0.42$ kpc, in excellent agreement with the distance calculated using the RR Lyrae stars, and consistent with estimates in the literature.

5.3. Metallicity

Although the relation of [Sandage 2006], relating the mean period of RR0 stars to the cluster metallicity is not applicable for Oosterhoff type II clusters [Clement et al. 2001], we can use the metallicities we calculated in Sec. 4.1 for the RR Lyrae stars in the cluster to derive an estimate for the metallicity of M 30. To do this, we simply compute an average of the RR Lyrae metallicities given in Table 7, excluding the variables for which the metallicity estimate is unreliable. Assuming that there is no systematic offset between the different types of variables, as in previous studies ([Kains et al. 2012], [Bramich et al. 2011]), we find a mean metallicity $[\text{Fe/H}]_{ZW} = -2.01 \pm 0.04$, in good agreement with values found in the literature (see Table 4).

[Carretta et al. 2009a] derived a new metallicity scale based on GIRAFFE and UVES spectra of red giant branch (RGB) stars in 19 globular clusters, which is now widely used to quote metallicity values for globular clusters. The transformation from the ZW to the UVES ([Carretta et al. 2009a]) scale is given as

$$[\text{Fe/H}]_{\text{UVES}} = -0.413 + 0.130 [\text{Fe/H}]_{ZW} - 0.356 [\text{Fe/H}]_{ZW}^2.$$

Using this we find a metallicity for M 30 of $[\text{Fe/H}]_{\text{UVES}} = -2.11 \pm 0.06$, significantly higher than the value found for this cluster by [Carretta et al. (2009a)] of $[\text{Fe/H}]_{\text{UVES}} = -2.34 \pm 0.05$.

5.4. Age

We use our CMD to derive an estimate for the age of M 30, by fitting to it the isochrones of [VandenBerg & Clem 2003], using our estimate of the cluster metallicity, $[\text{Fe/H}]_{ZW} = -2.01 \pm 0.04$. We also used a value for the $\alpha$-enhancement of $[\alpha/\text{Fe}] = +0.2$ ([Dotter et al. 2010]). From the best-fitting isochrones, we estimate the age of the cluster to be $13.0 \pm 1.0$ Gyr, in good agreement with recent estimates in the literature (see Table 10). A set of isochrones is overplotted on the CMD in Fig. 7.

6. Conclusions

We have used V and I-band observations spanning a baseline of $\sim 14$ months to survey stellar photometric variability in M 30. This allows us to update the catalogue of variables in this cluster significantly, with detections and refined analysis of three previously known RR Lyrae stars, one known U Gem star, as well as of two candidate RR Lyrae stars, to which we assigned catalogue numbers. Furthermore, we detect previously unknown variables, including two RR1 stars, an SX Phoenicis star, an eclipsing blue straggler system, and two variables that we are unable to classify with certainty. We provide refined period estimates for all variables, and then carry out Fourier decomposition of RR Lyrae stars. Using the Fourier parameters of stars for which this was successful, we derive properties for the RR Lyrae, and use these as proxies for the cluster’s properties.

We find a cluster metallicity of $[\text{Fe/H}]_{ZW} = -2.01 \pm 0.04$, or $[\text{Fe/H}]_{\text{UVES}} = -2.11 \pm 0.06$, and distances of $8.32 \pm 0.20$ or 8.10 kpc, using RR0 and RR1 stars respectively. Our light curve of the SX Phoenicis variable V20 also affords another way to estimate the cluster distance; using this, we find a distance of $8.35 \pm 0.42$ kpc. Our CMD also allows us to estimate the age of the cluster by fitting isochrones to it. We find an age of $13 \pm 1$ Gyr. All of these values are in good agreement with estimates in the literature, and are independent estimates calculated for the first time using Fourier decomposition of RR Lyrae in this cluster.
