Abstract
We analyse the finite-time blow-up of solutions of the heat flow for $k$-corotational maps $\mathbb{R}^d \to S^d$. For each dimension $d > 2 + k(2 + 2\sqrt{2})$ we construct a countable family of blow-up solutions via a method of matched asymptotics by glueing a re-scaled harmonic map to the singular self-similar solution: the equatorial map. We find that the blow-up rates of the constructed solutions are closely related to the eigenvalues of the self-similar solution. In the case of 1-corotational maps our solutions are stable and represent the generic blow-up.

Keywords: type II, matched asymptotics, singularity, parabolic, harmonic map flow

Introduction
A map $F : M \to N \subset \mathbb{R}^d$ between two compact Riemannian manifolds $M$ and $N$ is called harmonic if it is a critical point of the functional

$$E(F) = \frac{1}{2} \int_M |\nabla F|^2 \, dV_M.$$ 

The heat flow for harmonic maps was introduced by Eells and Sampson [7] as a method of deforming any smooth map $F_0$ to a harmonic map via the equation

$$\frac{\partial}{\partial t} F = (\Delta F)^\top, \quad F|_{t=0} = F_0,$$ 

(1)
where \((\Delta F)^+\) is a projection of \((\Delta F) \in \mathbb{R}^k\) to \(T_F N\)—a tangent space to \(N\) at the point \(F\). For any solution to (1) we have

\[
\frac{d}{dt}E(F) = -\int_M |\partial_t F|^2 \, dV_M \leq 0.
\]

If the flow exists for all times, \(E(F) \geq 0\) converges to some \(E_\infty\), suggesting that \(F \to F_\infty\) with \(F_\infty\) being a harmonic map. This approach proved to work only for target manifolds \(N\) with non-positive sectional curvature. If there is a point in \(N\) with positive sectional curvature, the gradient of a solution to (1) may blow-up in a finite time. In consequence, existence of global in time solutions may be established only in a weak sense [6]. Moreover, the uniqueness of solutions can no longer be guaranteed [6]. For explicit examples of non-unique weak solutions to (1) in the case of maps \(\mathbb{R}^d \to S^d\) with \(3 \leq d \leq 6\) see [3] and [10].

In order to overcome the problems posed by a finite-time blow-up and to investigate the circumstances in which the uniqueness is lost one has to fully understand the blow-up mechanism. The most general classification of solutions with a blow-up divides them into two types. We call a solution \(F\) to (1) that blows up in finite time \(T\) to be of type I if there exists a constant \(C\) such that

\[
(T - t) \sup_M |\nabla F|^2 \leq C
\]

holds for \(t < T\) where \(T\) is the blow-up time; if (2) does not hold the blow-up is of type II.

The reason for this classification becomes clear when we take maps \(\mathbb{R}^d \to N\). Then, if the blow-up is of type I, we know that \(F(x,t) = w(\frac{x - x_0}{\sqrt{T - t}})\) near an isolated singularity located at \((x_0, T)\) [18, p 293]. The function \(w : \mathbb{R}^d \to N\) describes the profile of a singular solution \(F\) and the question of existence of singular solutions of type I reduces to the question of existence of admissible profile functions \(w\). When the blow-up is of type II there is no similar universal description of what \(F\) looks like near the singularity and any type II solution has to be considered on a case by case basis.

A careful reader will notice that \(\mathbb{R}^d\) is not a compact manifold. Because in this paper we consider only isolated singularities it is a matter of convenience to replace the compact domain \(M\) with a non-compact tangent space \(T_{x_0}M = \mathbb{R}^d\), i.e. to neglect the curvature of the domain. Such simplification does not affect the blow-up mechanism.

Let us consider the simplest positively curved target, \(S^d\) embedded in \(\mathbb{R}^{d+1}\) in a canonical way. The deformation of a map \(\mathbb{R}^d \to S^d\) according to the harmonic map heat flow (1) simplifies to

\[
\partial_t F = \Delta F + |\nabla F|^2 F.
\]

Let us introduce spherical coordinates \((r, \omega)\) on \(\mathbb{R}^d\) and coordinates \((u, \Omega)\) on \(S^d\), with \(u\) denoting the latitudinal position on \(S^d\) and \(\Omega \in S^{d-1}\) parametrizing the equator. Using these coordinates we can further restrict \(F\) to a highly symmetric class of \(k\)-corotational maps

\[
(r, \omega) \mapsto (u(r, t), \Omega_k(\omega)).
\]

\(\Omega_k\) is a (non-constant) harmonic map with a constant energy density \(\|\nabla \Omega_k\|^2 = k(k + d - 2)\), the number \(k = 1, 2, 3, \ldots\) corresponds to a topological degree of map (4). The class of \(k\)-corotational maps is preserved by the harmonic map flow and the ansatz (4) reduces (3) to

\[
\partial_r u = \frac{1}{r^{d-1}} \partial_r \left( r^{d-2} \partial_r u \right) - \frac{k(d + k - 2)}{2r^2} \sin(2u).
\]

The Dirichlet energy \(E(F)\) can be expressed (up to a multiplicative constant) in terms of \(u\) as

\[
E(u) = \frac{1}{2} \int_0^\infty \left( \partial_r u \right)^2 + k(d + k - 2) \frac{\sin^2(u)}{r^2} \right) r^{d-1} \, dr.
\]
Regularity of \( F \) enforces a boundary condition \( u(0, t) = 0 \), while boundary condition at \( r = \infty \) follows from the finiteness of Dirichlet energy \( E(u) < \infty \). The monotonicity of energy

\[
\frac{d}{dt} E(u) = -\int_0^\infty (\partial_r u)^2 r^{d-1} \, dr \leq 0
\]

ensures that the blow-up can happen only at \( r = 0 \). Let us define \( R(t) \) as the smallest spatial scale involved in the blow-up (obviously, \( R(t) \to 0 \) with \( t \to T \)). When we approach the blow-up time, the solution on the scale \( r = \mathcal{O}(R(t)) \) looks like \( u(r, t) = Q(\frac{r}{R(t)}) \) for some fixed profile \( Q \). This motivates the following definition of a blow-up rate

\[
R(t) = \frac{1}{\sup_{r>0} |\partial_r u(r, t)|}.
\]

By the definition (8) of the blow-up rate \( R(t) \), a re-scaled solution \( u(r/R(t), t) \) has a bounded gradient for all times \( t < T \):

\[
\sup_{r>0} |\partial_r u(r/R(t), t)| = 1.
\]

The blow-up mechanisms governed by (5) depend heavily on \( k \) and \( d \) and can be either type I or type II. For \( k \)-corotational maps in dimension \( d = 2 \) van den Berg, Hulshof and King [19] derived formal results for blow-up rates. In particular, for 1-corotational maps, they conjectured that the generic blow-up is of type II with the blow-up rate

\[
R(t) \sim \frac{(T - t)^{1/2}}{\log(T - t)^{\omega}} \quad \text{as } t \nearrow T.
\]

Recently, this result has been proved by Raphael and Schweyer [16] by using methods coming from analysis of dispersive equations. For 1-corotational maps in dimension 2 other, non-generic blow-up rates, are also possible [1].

For 1-corotational maps in dimensions \( 3 \leq d \leq 6 \) Fan [8] used ODE methods to prove the existence of a countable family \( \{f_n\}_{n=1,2,...} \) of self-similar solutions for which

\[
R(t) \sim (T - t)^{\frac{1}{2}}.
\]

Later, Biernat and Bizoń [3] showed, via numerical and analytical methods, that only \( f_1 \) is linearly stable and corresponds to a generic type I blow-up. Gastel [9] proved that the solution \( f_1 \) exists also for \( k \)-corotational maps as long as \( 3 \leq d < 2 + k(2 + 2\sqrt{2}) \). On the other hand, there are no results in the literature on dimensions \( d > 2 + k(2 + 2\sqrt{2}) \), even for 1-corotational maps.

Statement of the main result

In our paper we use a method of matched asymptotics to construct a generic type II solution for 1-corotational maps in dimensions \( d \geq 7 \). As \( t \nearrow T \), the blow-up rates of these solutions are asymptotically given by

\[
R(t) \sim \frac{C(T - t)^{\frac{1}{2}}}{-\log(T - t) - \kappa} \quad \text{for } d = 7
\]

\[
R(t) \sim \kappa (T - t)^{\frac{1}{2} + \beta_1} \quad \text{for } d > 7,
\]

with \( \beta_1 > 0 \) defined as

\[
\beta_1 = \frac{1}{2} + \frac{2}{d - 2 - \omega}, \quad \omega = \sqrt{d^2 - 8d + 8}.
\]
For each blow-up rate the constant $\kappa$ represents the dependence on initial data, while in (9) the constant $C$ is a fixed number. Interestingly, the blow-up rate in dimension $d = 7$ is, to the leading order, equal to

$$R(t) = \frac{C(T - t)^{\frac{1}{2}}}{-\log(T - t)}(1 + \mathcal{O}(|\log(T - t)|^{-1})), \quad t \nearrow T$$

so, in dimension 7, the blow-up rate is asymptotically independent of initial data.

Dimension $d = 7$ can be seen as a borderline between type I and type II blow-ups. If one forgets about the underlying geometric setup and allows for non-integer values of $d$, then all our results remain valid. For $d$ slightly less than 7 numerical evidence indicates a presence of a generic type I blow-up. On the other hand, when $d$ approaches 7 from above, $\beta_1$ continuously drops to zero. So for $d < 7$ we have a type I blow-up but for all $d > 7$ we have a power-law type II blow-up of the form (10). Naively, one could arrive to a conclusion that for $d = 7$ we should have a type I blow-up. Instead, we get a type II blow-up (9) corresponding to a type I blow-up rate with a logarithmic correction. The transition from type I to type II solution at $d = 7$ also indicates that the self-similar solutions to (9) cease to exist for $d \geq 7$; but analysis of these vanishing self-similar solutions is beyond the scope of this paper.

In fact, the results for 1-corotational maps are a special case of a more general result for $k$-corotational maps that we derive. For $k$-corotational maps with dimension $d$ and any positive integer $N$ satisfying

$$R_N(t) \sim \kappa(T - t)^{\frac{1}{2} + \beta_N} \quad \text{for} \quad d > 2 + k(2 + 2\sqrt{2})$$

$$N > \frac{1}{4}(d - 2 - \omega),$$

$$R_N(t) = \frac{C(T - t)^{\frac{1}{2}}}{(-\log(T - t) + s_0)^{\frac{1}{2}}} \quad \text{for} \quad d > 2 + k(2 + 2\sqrt{2})$$

$$N = \frac{1}{4}(d - 2 - \omega),$$

with $\beta_N > 0$ defined as

$$\beta_N = -\frac{1}{2} + \frac{2N}{d - 2 - \omega}, \quad \omega = \sqrt{(d - 2(k + 1))^2 - 8k^2}$$

and $\delta > 0$ equal to

$$\delta = \min(\omega, d - 2 - \omega).$$

From the dynamical system point of view, each of these solutions corresponds to a saddle point with $N - 1$ unstable directions. The constants $\kappa$ and $s_0$ depend on initial data, while $C$ is a function of $d$ and $k$ only. This means that asymptotically blow-up rate (50) is universal for all initial data:

$$R_N(t) = \frac{C(T - t)^{\frac{1}{2}}}{(-\log(T - t))^\frac{1}{2}}(1 + \mathcal{O}(|\log(T - t)|^{-1})), \quad t \nearrow T.$$
As in the papers of Herrero and Velázquez, the blow-up rates are closely connected to the eigenvalues of a singular self-similar solution. In the case of $k$-equivariant harmonic maps, this singular solution is remarkably simple, as it corresponds to a singular equatorial map $u(r, t) = \pi/2$. The eigenvalues coming from linearization around the equatorial map $(\lambda_N = -\frac{d-2}{2} - \omega^2 + N$ for $N = 0, 1, 2, \ldots$, see also (30)) relate to the blow-up rate exponents via $\beta_N = \frac{\lambda_N}{d-2-\omega}$. The interesting case of neutral eigenvalues, $\lambda_N = 0$, requires us to include nonlinear corrections into our analysis and gives rise to the logarithmic terms in the blow-up rate (50). Because there are two ways in which the nonlinear term can enter the equation, we have to estimate both of them and decide which is the dominant one. Surprisingly, this dominance—and thus the blow-up mechanism—is not set in stone but it depends on the dimension, which is reflected by a peculiar formula (14).

The formal solutions constructed in this paper are a first step towards the rigorous proof of existence of type II blow-up for the equations of heat flow for $k$-corotational harmonic maps. The solutions presented here will be proved to exist in the upcoming paper by the author and Yukihiro Seki [4]. The proof bases on topological methods similar to the ones used by Herrero and Velazquez in [11].

**Construction of a blowing up solutions**

**Preliminaries**

To describe blow-up at time $T$ it is convenient to introduce the self-similar variables

$$ y = \frac{r}{\sqrt{T-t}}, \quad s = -\log(T-t), \quad f(y, s) = u(r, t) \quad (15) $$

in which the original equation (5) takes the following form

$$ \partial_s f = \partial_y f + \left(\frac{d-1}{y} - \frac{y}{2}\right) \partial_y f - \frac{k(d+k-2)}{2y^2} \sin(2f). \quad (16) $$

The boundary condition $u(0, t) = 0$ trivially carries over as $f(0, s) = 0$.

Self-similar solutions are stationary points of the above equation, if they exist they fully capture the blow-up rate (i.e. the solution is regular for all $s$ including $s = \infty$). For 1-corotational maps a countable family $\{f_n\}_{n=1,2,\ldots}$ of self-similar solutions was proved to exist for $3 \leq d \leq 6$ by Fan [8]. Biernat&Bizoń [3] demonstrated that only the first member of the family, $f_1$, is linearly stable. Numerical evidence suggests that for $d \geq 7$ these solutions are absent and therefore the type I blow-up is no longer possible. For higher topological degrees the only rigorous result on existence of self-similar solutions, that authors are aware of, is the one by Gastel [9] who proved the existence of the monotone self-similar solution $f_1$ in dimensions $d \leq 2 + k(2 + 2\sqrt{2})$. Numerical evidence suggests, that for all $k \geq 1$ and $d \leq 2 + k(2 + 2\sqrt{2})$ there exists a countable family of self-similar solutions $\{f_n\}_{n=1,2,\ldots}$.

On the other hand, in any dimension $d$ and for any topological degree $k$ (16) there exists a singular stationary solution, $f(y, s) = \pi/2$. This solution is singular because it violates the boundary conditions at $y = 0$. Linear stability of this solution heavily depends on $d$ and $k$. For $k = 1$ and dimension $d \geq 7$, $f(y, s) = \pi/2$ is linearly stable (up to a gauge mode corresponding to the shift of blow-up time $T$). For $k \geq 2$ and $d \geq 2 + k(2 + 2\sqrt{2})$, $f(y, s) = \pi/2$ loses some stability and becomes a saddle point with a finite number of unstable directions. As we shall see, this solution plays the key role in the dynamics of the blow-up.
Boundary layer

The singular solution $f(y, s) = r/2$ serves as a starting point for our construction of a type II blow-up. The first step is to assume that the constructed solution converges to $r/2$. The convergence to $r/2$ has to be non-uniform because of the boundary condition at the origin $f(0, s) = 0$. The non-uniform convergence can be realized by a boundary layer of size $\epsilon(s)$ near the origin, where a rapid transition from $f = 0$ to $f = r/2$ occurs. This transition can be described by changing variables in (16) to

$$
\xi = \frac{y}{\epsilon(s)}, \quad U(\xi, s) = f(y, s),
$$

(17)

where the dependent variable $U$ solves

$$
\epsilon^2 \partial_{\xi} U = \partial_{\xi \xi} U + \left( \frac{d - 1}{\xi} + (2\epsilon \dot{\epsilon} - \epsilon^2) \frac{\xi}{2} \right) \partial_{\xi} U - \frac{k(d + k - 2)}{2\xi^2} \sin(2\xi), \quad U(0, s) = 0.
$$

(18)

We expect convergence to $r/2$, so the width of the boundary layer must tend to zero with time, hence $\epsilon(s) \to 0$ for $s \to \infty$. Additionally, we assume that the derivative of $\epsilon$ is bounded by $\epsilon$ for large $s$ i.e. $\dot{\epsilon}(s) = O(\epsilon(s))$ as $s \to \infty$. Under these assumptions one can drop the quadratic terms in $\epsilon$ and $\dot{\epsilon}$ from equation (18). This leads to a solution $U(\xi, s) = U^*(\xi)$, where $U^*(\xi)$ solves an ordinary differential equation

$$
\frac{d^2 U^*}{d\xi^2} + \frac{d - 1}{\xi} \frac{dU^*}{d\xi} - \frac{k(d + k - 2)}{2\xi^2} \sin(2U^*) = 0
$$

(19)

with boundary condition $U^*(0) = 0$ inherited from (18). Any $U^*$ solving (19) is also a stationary point of (5), i.e. $U^*$ is a $k$-corotational harmonic map.

Equation (19) possesses a scaling symmetry $\xi \to \lambda \xi$ (with $\lambda > 0$), which implies that any $U_{\lambda}(\xi, s) = U^*(\lambda \xi)$ is also an admissible approximate solution to (18). To get rid of this ambiguity, we first notice, that any regular solution to (19) behaves like $U^*(\xi) = a\xi^k + O(\xi^{3k})$ near the origin with some real $a$. We can fix the scaling freedom by setting $a = 1$, or equivalently by introducing an additional boundary condition

$$
U^*(\xi) = \xi^k + O(\xi^{3k}) \quad \text{as} \quad \xi \to 0.
$$

(20)

Equation (19) simplifies to an autonomous system if we use variables $x$ and $v$ defined as $\xi = e^x$ and $2U^*(\xi) = \pi + v(x)$

$$
v'' + (d - 2)v' + k(d + k - 2) \sin(v) = 0.
$$

(21)

The boundary condition $U^*(\xi) = \xi^k + O(\xi^{3k})$ implies $v(x) = -\pi + e^{kx} + O(e^{3kx})$ when $x \to -\infty$. Because (21) is an autonomous equation we can deduce some global properties of $U^*$ by analysing the phase diagram of (21).

The solution to (21) subject to these boundary conditions has a mechanical interpretation of a motion of a damped pendulum with $v$ being the angular position and $x$ corresponding to the time. The boundary conditions demand that the pendulum starts inverted, $v = -\pi$, at time $x = -\infty$ and swings out of this unstable position. The damping term forces the pendulum to reach the bottom, $v = 0$, when $x = \infty$. In the phase plane spanned by $(v, v')$, this trajectory is a heteroclinic orbit starting at the saddle point $(-\pi, 0)$ and ending at $(0, 0)$. To get the asymptotic behaviour of $U^*$ as $\xi \to \infty$ it is enough to linearize (21) at the endpoint of the heteroclinic orbit, as shown in figure 1.

To analyse the asymptotic behaviour of $v(x)$ for $x \to \infty$ we linearize the equation (21) at the stationary point $(0, 0)$. The eigenvalues of the linearized equation are

$$
\mu_+ = -\gamma, \quad \mu_- = -\gamma - \omega
$$

(22)
Figure 1. Phase diagram for the equation \(0 = v'' + (d - 2)v' + k(d + k - 2)\sin(v)\) with \(k = 1\) and \(d = 8\). A solution joining two critical points of the phase diagram is shown as a dashed line. Additionally, the plot depicts a trapping region \(S = \{(v, v') | k\sin(v) \leq v' \leq \gamma\sin(v)\}\), from which no solution can escape (here \(\gamma = \frac{1}{2}(d - 2 - \sqrt{(d - 2(k + 1))^2 - 8k^2}) = 3 - \sqrt{2}\)). The trapping region \(S\) is used to prove estimates on a depicted solution in theorem 1.

with constants \(\gamma = \frac{1}{2}(d - 2 - \omega)\) and \(\omega = \sqrt{(d - 2(k + 1))^2 - 8k^2}\). From the form of the eigenvalues \(\mu_\pm\) we see that the stationary point \((0, 0)\) is a stable spiral for \(d < d^* = 2 + k(2 + 2\sqrt{2})\) but changes to a stable node when \(d \geq d^*\). It follows that the asymptotic behaviour of \(v\), and consequently of \(U^*\), can be either oscillatory or non-oscillatory depending on \(d\) for a given \(k\). To proceed with our construction, we have to assume the latter—non-oscillatory—behaviour, that is \(d \geq d^*\). For the particular case of 1-corotational maps this condition simplifies to \(d \geq 7\), if we consider only integer values of \(d\).

There is one last thing to establish before we can make a claim about the asymptotic behaviour of \(U^*\). The formula for asymptotic behaviour of \(v\) near \((0, 0)\), written explicitly, is

\[
v(x) = 2h_+ \cdot e^{i\mu_+} (1 + O(e^{-2\gamma}))) + 2h_- \cdot e^{i\mu_-} (1 + O(e^{-2\gamma}))
\]  
(23)

(the factor of 2 is a matter of convenience). Because \(\mu_+ > \mu_-\), the leading order term should be \(2h_+ e^{i\mu_+}\), unless \(h_+\) is zero, in which case the dominant behaviour changes to \(2h_- e^{i\mu_-}\). In the appendix (theorem 1) we exclude this possibility by proving that that \(h_+\) is negative. We finally conclude that the asymptotic behaviour of \(U^*\) for large \(\xi\) is

\[
U^*(\xi) = \frac{\pi}{2} - h\xi^{-\gamma} (1 + O(\xi^{-2}) + O(\xi^{-\omega})),
\]  
(24)

with \(h = -h_+ > 0\) depending only on \(d\), and \(\gamma > 0\) defined as \(-\mu_+\):

\[
\gamma = \frac{1}{2}(d - 2 - \omega), \quad \omega = \sqrt{d^2 - 8d - 8}.
\]  
(25)

Let us check where the approximation of \(U(\xi, s)\) by \(U^*(\xi)\) is valid. To arrive at the approximate equation (19) we had to drop the terms containing \(\epsilon\) and \(\dot{\epsilon} = O(\epsilon)\). The approximation fails if one of the dropped terms becomes comparable with the remaining terms. For example we assumed that the remainder term in

\[
\left(\frac{d - 1}{\xi} + (2\epsilon\dot{\epsilon} - \epsilon^2)\frac{\xi}{2}\right) = \frac{d - 1}{\xi} (1 + O(\epsilon^2))
\]  
(23)

is
is small. But this assertion clearly fails for \( \xi \) of order \( 1/\epsilon \), so the approximation \( U(\xi, s) \approx U^*(\xi) \) can be valid only if \( \xi \ll 1/\epsilon \) or, by definition (17), if \( y \ll 1 \).

**Linearization around the singular solution**

The boundary layer from the previous section resolves a conflict between the boundary condition \( f(0, s) = 0 \) and the assumed convergence of \( f(y, s) \) to \( \pi/2 \). In this section, we focus on describing the solution to (16) away from the boundary layer, i.e. for \( y \) of order 1. For such \( y \), we expect the solution to stay close to \( f = \pi/2 \), so it is convenient to introduce a new variable \( \psi \) defined as

\[
f(y, s) = \frac{\pi}{2} + \psi(y, s).
\]

The new variable \( \psi \) solves

\[
\partial_s \psi = -A \psi + F(\psi), \quad F(\psi) = k(d + k - 2) \frac{(\sin(2\psi) - 2\psi)}{y^2} = \mathcal{O}(\psi^3)
\]

with operator \( A \) given by

\[
-A \psi = \frac{1}{\rho} \partial_y \left( \rho \partial_y \psi \right) + k(d + k - 2) \frac{\psi}{y^2} \psi, \quad \rho(y) = y^{d-1}e^{-y^2/4}.
\]

A natural Hilbert space, arising in the context of operator \( A \) is

\[
L^2(\mathbb{R}_+, \rho \, dy) = \left\{ f \in L^2_{\text{loc}}(\mathbb{R}_+) \mid \int_0^\infty f(y)^2 \rho(y) \, dy < \infty \right\}
\]

with a canonical inner product

\[
\langle f, g \rangle = \int_0^\infty f(y)g(y)\rho(y) \, dy.
\]

It is routine to check that the operator \( A \), under the assumption \( d > 2 + k(2 + 2\sqrt{2}) \), is self-adjoint in \( L^2(\mathbb{R}_+, \rho \, dy) \) with domain \( H^1(\mathbb{R}_+, \rho \, dy) \)—a weighted Sobolev space defined in a canonical way.

To find the eigenfunctions of \( A \) we have to solve an ordinary differential equation

\[
\frac{1}{\rho} \frac{d}{dy} \left( \rho \frac{d}{dy} \phi \right) + \frac{k(d + k - 2)}{y^2} \phi = -\lambda \phi
\]

with the condition \( \phi \in H^1(\mathbb{R}_+, \rho(y) \, dy) \). After a change of variables \( \phi(y) = y^{-\gamma} w(y^2/4) \) and \( z = y^2/4 \) (with \( \omega \) and \( \gamma \) defined in (25)) equation (28) becomes

\[
z \frac{d^2 w}{dz^2} + \left( 1 - z + \frac{\omega}{2} \right) \frac{d w}{dz} = - \left( \lambda + \frac{\gamma}{2} \right) w.
\]

with the condition \( w \in H^1(\mathbb{R}_+, e^{-z}z^{1+\omega/2} \, dz) \). Combination of the latter condition and the eigenvalue problem (29) leads to \( w(z) = L_n^{(\omega/2)}(z) \) with \( \lambda_n + \gamma/2 = n \) \( n = 0, 1, 2, \ldots \), where \( L_n^{(\omega/2)}(z) \) denotes associated Laguerre polynomials. In terms of \( \phi \) and \( y \) these results read

\[
\phi_n = N_n y^{-\gamma} L_n^{(\omega/2)}(y^2/4), \quad \lambda_n = -\gamma/2 + n, \quad n = 0, 1, 2, \ldots.
\]

The normalization constant

\[
N_n = 2^{-1-\omega/2} \sqrt{\frac{\Gamma(n+1)}{\Gamma(n+1+\omega/2)}}
\]

(31)
assures the orthonormality condition $\langle \phi_n, \phi_m \rangle = \delta_{n,m}$. For completeness we shall add that the behaviour of $\phi_n$ near the origin is $\phi_n = c_n y^{-\gamma} (1 + O(y^{-2}))$, $c_n = 2^{-1-\omega/2} \Gamma(1 + \omega/2) \Gamma(1 + n + \omega/2) / \Gamma(1 + n)$.

(32)

Given the orthogonality relation and completeness of $\phi_n$ we can represent any solution to (26) as the following series

$$\psi(y, s) = \sum_{n=0}^{\infty} a_n(s) \phi_n(y).$$

(33)

In the above expression $a_n(s)$ solve nonlinear equations

$$\dot{a}_n = -\lambda_n a_n + \langle F(\psi), \phi_n \rangle \quad \text{for } n = 0, 1, 2, \ldots$$

(34)

with $\dot{a}_n$ standing for the derivative of $a_n$ with respect to $s$ and $F(\psi)$ is defined in (26). Unfortunately, the presence of the nonlinear coupling term $\langle F(\psi), \phi_n \rangle$ renders (34) impossible to solve in its current form. In the next section we will make assumptions on the form of $\psi$, that will allow us to estimate the nonlinear term. Consequently, we will be able to produce an approximate solution to (16).

**Construction of a global solution**

The analysis of the boundary layer solution gives us an approximation

$$f(y,s) \approx f_{inn}(y, s) = U^* \left( \frac{y}{\epsilon(s)} \right) \quad \text{for } y \ll 1.$$  

(35)

If we take $\epsilon \ll y \ll 1$ we can use the asymptotic formula (24) for $U^*$ to get

$$f_{inn}(y, s) = \pi/2 - h \epsilon(s)^{y^{-\gamma}}$$

(36)

to the leading order. Because $\epsilon(s) \to 0$ with $s \to \infty$, the inner solution $f_{inn}(y, s)$ can get arbitrarily close to $\pi/2$ for a fixed $y$. But if $f(y, s)$ is close to $\pi/2$ the eigenfunctions of the linear operator $A$ should work as a good approximation to the solution $f(y, s)$, so we write

$$f(y, s) \approx f_{out}(y, s) = \pi/2 + \sum_{n=0}^{\infty} a_n(s) \phi_n(y) \quad \text{for } y \gg \epsilon(s).$$

(37)

Without further assumptions, equations (34) for the coefficients $a_n$ cannot be solved. To proceed with our construction we have to reduce the number of independent degrees of freedom; we achieve this by assuming that one coefficient, say $a_N$, dominates the others, i.e.

$$|a_N(s)| \gg |a_n(s)| \quad \text{for } n \neq N, \quad \text{and } s \to \infty.$$  

(38)

By (38) the outer solution is dominated by only one eigenfunction $\phi_N$ for large $s$

$$f(y, s) \approx f_{out}(y, s) = \pi/2 + a_N(s) \phi_N(y) \quad \text{for } y \gg \epsilon(s).$$

(39)

So far, this is the most arbitrary assumption we make, so it is critical to ensure that it does not lead to a contradiction at the end of the construction. In one of the following sections we verify this assumption and show which conditions on initial data does (38) require. This analysis leads to conclusions regarding the stability of constructed solutions.

Both approximations $f_{inn}$ and $f_{out}$ are compatible in the region $\epsilon \ll y \ll 1$ if we impose a relation between $a_N(s)$ and $\epsilon(s)$. Indeed, the outer solution behaves like

$$f_{out}(y, s) = \frac{\pi}{2} + a_N(s) \phi_N(y) = \frac{\pi}{2} + c_N a_N(s) y^{-\gamma} (1 + O(y^{\gamma})).$$

(40)
Figure 2. A snapshot at $s = 13$ of a numerical solution $f(y, s)$ (in dimension $d = 8$) compared to an approximation via inner and outer solutions combined into $f_1(y, s)$ (see definition (42)). The inner solution, $f_{inn}(y, s)$, is a good approximation for $y \ll 1$, while the outer solution, $f_{out}(y, s)$, is a good approximation when $f(y, s)$ is close to $\pi/2$. Both solutions coincide near a point $y = K = 10^{-1}$.

(see (32)) and by comparing (40) with (36) we can choose $\epsilon$ such that

$$c_N a_N(s) = -h\epsilon(s)^\gamma.$$  \hfill (41)

Equation (41) is called the matching condition and it serves as a link between the inner solution and the outer solution.

Given solutions (35) and (39), together with condition (41), we can construct a global approximate solution, which is valid for all $y$,

$$f_N(y, s) = \begin{cases} f_{inn}(y, s) = U^\ast \left( \frac{\sqrt{y}}{\epsilon(y)} \right) & \text{for } y \leq K \\ f_{out}(y, s) = \pi/2 - \frac{h}{c_N} \epsilon(s)^\gamma \phi_N(y) & \text{for } y > K \end{cases}$$  \hfill (42)

with $K$ chosen so that $\epsilon \ll K \ll 1$ (e.g. $K = \sqrt{\epsilon}$). For an example of $f_N$ see figure 2.

At this point, we have an ansatz for a global solution with one unknown—function $\epsilon$. To get $\epsilon$ we have to go back to (34), with $n = N$ and $a_N(s) = -\epsilon(s)^\gamma h/c_N$ and solve

$$\gamma \dot{\epsilon} = -\lambda_N \epsilon - \frac{c_N}{h} \epsilon^{1-\gamma} \langle F(\psi), \phi_N \rangle \quad \psi = f_N(y, s) - \pi/2.$$  \hfill (43)

The remaining question is in what way does the nonlinear term $\langle F(\psi), \phi_N \rangle$ enter the equation? To answer this question we have to split $\langle F(\psi), \phi_N \rangle$ into contributions from inner and outer solutions. However, these computations are too technical for this section and would break the flow of the argument. Instead, we enclose the derivation in the next section and present the resulting formula here

$$\langle F(\psi), \phi_N \rangle = D_N \epsilon^{\gamma + \delta}, \quad \delta = \min(\omega, 2\gamma) > 0, \quad D_N > 0.$$  \hfill (44)
Combination of the estimate (44) and the equation (43) yields the following equation for $\epsilon$

$$\gamma \dot{\epsilon} = -\lambda_N \epsilon - \frac{D_N c_N}{h} \epsilon^{1+\delta}.$$  \hspace{1cm} (45)

We can immediately discard negative eigenvalues $\lambda_N$, as they lead to $\epsilon$ which does not tend to zero; such $\epsilon$ violates our previous assumptions about the boundary layer.

The only viable solutions are those with $\lambda_N \geq 0$, which leads to two further cases. When $\lambda_N > 0$ the nonlinear term is of higher order and can be discarded for $s$ large enough leading to

$$\epsilon(s) = \epsilon_0 e^{-\frac{\lambda_N}{h} s} \quad \text{for} \quad \lambda_N > 0$$  \hspace{1cm} (46)

with $\epsilon(0)$ depending on initial data. On the other hand, when $\lambda_N = 0$ the nonlinear term becomes the leading order term resulting in

$$\epsilon(s) = C_N (s - s_0)^{1/\delta} \quad \text{for} \quad \lambda_N = 0.$$  \hspace{1cm} (47)

We can now relate the blow-up rate $R(t)$ with $\epsilon$ via

$$R(t) = \frac{1}{\sup_{t \geq 0} |\partial_t u(r, t)|} = C_s \sqrt{T - t} \epsilon(s), \quad C_s = \frac{1}{\sup_{t \geq 0} |\frac{d}{dt} (\xi(t))|}.$$  \hspace{1cm} (48)

If we combine (48), (46) and (47), and solve the conditions $\lambda_N > 0$ and $\lambda_N = 0$ for $N$ we get the following blow-up rates

$$R_N(t) = C_s \epsilon_0 (T - t)^{1+\beta_N} \quad \text{for} \quad d > 2 + k(2 + 2\sqrt{2}) + \frac{1}{4} (d - 2 - \omega)$$  \hspace{1cm} (49)

$$R_N(t) = C_s C_N (T - t)^{1/\delta} \quad \text{for} \quad d > 2 + k(2 + 2\sqrt{2}) + \frac{1}{4} (d - 2 - \omega),$$  \hspace{1cm} (50)

with $\beta_N > 0$

$$\beta_N = -\frac{1}{2} + \frac{2N}{d - 2 - \omega}, \quad \omega = \sqrt{(d - 2(k + 1))^2 - 8k^2}$$  \hspace{1cm} (51)

and $\delta > 0$ being equal to

$$\delta = \min(\omega, d - 2 - \omega).$$  \hspace{1cm} (52)

**Approximation of the coupling term**

According to the assumed form of the global solution $f_N(y, s)$ we can approximate the solution $\psi$ in the intervals $y \leq K$ and $y > K$ separately. Therefore, we split the integral $\langle F(\psi), \phi_0 \rangle$ into

$$\langle F(\psi), \phi_0 \rangle = \left(\int_0^K + \int_K^{\infty}\right) F(\psi) \phi_0(y) y^{d-1} e^{-y^2/4} dy = I_{\text{inn}} + I_{\text{out}}.$$

We compute the two integrals $I_{\text{inn}}$ and $I_{\text{out}}$ and compare them to see which one gives the leading order contribution. Our analysis leads to two qualitatively different approximations of the nonlinear term

$$F(\psi) = \frac{k(d + k - 2)}{2y^2} (\sin(2\psi) - 2\psi)$$

depending on the choice of $d$ and $k$. 

177
The leading order term can be written as

\[ \xi d \]

for brevity we use a notation

\[ g(\xi) = \frac{k(d + k - 2)}{2} (\sin(2U^*(\xi) - \pi) - (2U^*(\xi) - \pi)). \]

When \( y < K \ll 1 \) we can replace the eigenfunction and the weight \( \phi_n(y) y^{d-1} e^{-\gamma y/4} \) with its leading order term \( \phi_n(y) e^{-\gamma y/4} (1 + \mathcal{O}(y^2)) \). We finally arrive at a simplified version of the integral \( I_{\text{inn}} \)

\[ I_{\text{inn}} \approx cn \int_0^K g(y/\epsilon) y^{d-3-\gamma} dy = cn \epsilon^{-2-\gamma} \int_0^{K/\epsilon} g(\xi) \xi^{d-3-\gamma} d\xi. \]  

The upper bound \( K/\epsilon \) in (53) tends to infinity as \( s \to \infty \), so it is reasonable to check whether the integrand is divergent or convergent as \( \xi \to \infty \). To this end we have to compute the asymptotic behaviour of \( g(\xi) \) at infinity. This can be done by using the asymptotic of \( U^* \), as given by (24)

\[ g(\xi) \approx -\frac{2k(d + k - 2)}{3} (U^*(\xi) - \pi/2)^3 \approx \frac{2k(d + k - 2)\epsilon^3}{3} \xi^{-3\gamma} \]  

as \( \xi \to \infty \).

The leading order of the integrand is thus \( \xi^{d-3-4\gamma} \). By definitions (25) of \( \gamma \) and \( \omega \) there holds

\[ d - 2 - \gamma = \gamma + \omega, \]  

so the leading order term can be written as \( \xi^{d-3-4\gamma} = \xi^{\omega-2\gamma-1} \).

We have to consider two cases, because the integral (53) can be divergent or convergent for large \( (K/\epsilon) \) depending on the sign of \( \omega - 2\gamma \). If \( \omega < 2\gamma \), then the integral converges so, by taking the limit \( K/\epsilon \to \infty \), we get

\[ I_{\text{inn}} = cn \epsilon^{-2-\gamma} \int_0^{\infty} g(\xi) \xi^{d-3-\gamma} d\xi = cn \epsilon^{-2-\gamma} \int_0^{\infty} g(\xi) \xi^{d-3-\gamma} d\xi. \]

But when \( \omega > 2\gamma \) the integral diverges as \( (K/\epsilon)^{\omega-2\gamma} \), so we can replace the integral with its rate of divergence, in which case the lowest order approximation is

\[ I_{\text{inn}} \approx \frac{2k(d + k - 2)\epsilon^3}{3} cn \epsilon^{-2\gamma} \left( \frac{K}{\epsilon} \right)^{\omega-2\gamma} = \frac{2k(d + k - 2)\epsilon^3 cn}{3} \epsilon^{-3\gamma} K^{\omega-2\gamma}. \]

We have to consider two similar cases when dealing with \( I_{\text{out}} \). For \( I_{\text{out}} \), \( \psi \) is dominated by its approximation via a single eigenfunction \( \psi = \frac{h}{cN} e^\gamma \phi_N \), which, together with \( y > K \), results in \( |\psi| \ll 1 \) near the origin. So, as the first step to the approximation of \( I_{\text{out}} \) we expand \( F \) in a Taylor series around \( \psi = 0 \)

\[ F(\psi) = F \left( \frac{h}{cN} e^\gamma \phi_N \right) \approx -\frac{k(d + k - 2)}{y^2} \left( \frac{h}{cN} e^\gamma \phi_N \right)^3 = \frac{2k(d + k - 2)\epsilon^3}{3y^2cN^3} e^{-3\gamma} \phi_N^3. \]

If we use the Taylor expansion in \( I_{\text{out}} \) we obtain

\[ I_{\text{out}} = \frac{2k(d + k - 2)\epsilon^3}{3cN^3} e^{-3\gamma} \int_K^\infty \phi_N(y)^3 \phi_n(y) y^{d-3-\gamma} e^{-\gamma y} dy, \]

178
which can be either divergent or convergent for small $K$. Near the origin ($y \to 0$) the leading order behaviour of the integrand is 
\[ \phi_N(y)^3 \psi_0(y) y^{d-3} e^{-\frac{y}{\gamma}} = (c_N)^3 c_n y^{d-3-4\gamma} (1 + O(y^2)) = (c_N)^3 c_n y^{3-2\gamma-1} (1 + O(y^2)). \]
It is clear, that for $\omega < 2\gamma$ the integral is finite and we can take the limit $K \to 0$, while for $\omega > 2\gamma$ the integral is divergent and behaves like $(c_N)^3 c_n K^{3-2\gamma}$. These two cases can be expressed as
\[ I_{\text{out}} \approx \frac{2}{3} k(d + k - 2)^{\gamma} c_n e^{-3\gamma} K^{3-2\gamma} \quad \text{for } \omega < 2\gamma, \]
and
\[ I_{\text{out}} \approx e^{-3\gamma} \frac{2k(d + k - 2)h^3}{\gamma} \int_0^\infty \phi_N(y)^3 \psi_0(y) y^{d-3} e^{-\frac{y}{\gamma}} dy \quad \text{for } \omega > 2\gamma. \]

We are now in a position to compare the contributions from $I_{\text{inn}}$ and $I_{\text{out}}$
\[ I_{\text{inn}} \propto e^{3\gamma}, \quad I_{\text{out}} \propto e^{\gamma + \omega}, \quad \text{for } \omega < 2\gamma, \]
\[ I_{\text{inn}} \propto e^{-3\gamma} K^{3-2\gamma}, \quad I_{\text{out}} \propto e^{3\gamma}, \quad \text{for } \omega > 2\gamma. \]

For sufficiently large times $I_{\text{inn}}$ dominates over $I_{\text{out}}$ when $\omega < 2\gamma$ because the term $(\epsilon/K)^{2\gamma - \omega}$ tends to zero. On the other hand, when $\omega > 2\gamma$ it is the other way around and $I_{\text{out}}$ dominates over $I_{\text{inn}}$ due to $K^{3-2\gamma} \to 0$. These two cases can be written in a unified way as
\[ \langle F(\psi), \phi_\delta \rangle \approx D_{\delta} e^{\gamma + \delta}, \quad \delta = \min(2\gamma, \omega). \]
with a constant
\[ D_{\delta} = \begin{cases} 
    c_n \frac{\gamma}{2(d - 1)^{\frac{3}{2}}} & \quad \text{for } \omega < 2\gamma, \\
    2(d - 1)^{\frac{3}{2}} c_n h^3 \int_0^\infty \phi_N(y)^3 \psi_0(y) y^{d-3} e^{-\frac{y}{\gamma}} dy & \quad \text{for } \omega > 2\gamma. 
\end{cases} \]

We intentionally avoided the case $\omega = 2\gamma$, for which both integrals diverge logarithmically. This happens only for a non integer dimension $d = \frac{7}{4}(7 + 2\sqrt{7}) \approx 8.194 \ldots$, which we can exclude as incompatible with underlying geometric setting of the heat flow for harmonic maps.

One possible interpretation of this phenomenon is a change of the way we should approximate the nonlinear term $F(\psi)$ before the projection onto $\phi_\delta$. For example, when $\omega > 2\gamma$, we can safely replace $F(\psi)$ with its Taylor expansion near $\psi = 0$, i.e.
\[ F(\psi) = \frac{2k(d + k - 2)}{\gamma^2} \psi^3. \]

Projecting $F(\psi)$ back to $\phi_\delta$ gives negligible contribution from $I_{\text{inn}}$ and significantly larger contribution from $I_{\text{out}}$. At the same time, the value of $I_{\text{out}}$ is proportional to the third power of amplitude of $\psi \propto a_N$: $I_{\text{out}} \propto e^{3\gamma} \propto a_N^3$.

As for the other case, $\omega < 2\gamma$, the contribution from the Taylor expansion is subdominant. Instead, a very small region $y < K$, of a diminishing size, governs the leading order behaviour of nonlinear term $F(\psi)$. We can replicate this effect by approximating $F(\psi)$ with a Dirac delta: $F(\psi) = G e^{\gamma + \delta} \delta(y)$. Indeed, to the leading order we get the same values for projections:
\[ \langle F(\psi), \phi_\delta \rangle = G e^{\gamma + \delta} \delta, \quad \delta = \min(2\gamma, \omega). \]

In fact, replacing the nonlinear term $F(\psi)$ with a Dirac delta is the starting point to several derivations of type II solutions [13,14]. On the other hand, the Taylor expansion rarely shows up in derivations of the blow-up rate.

To verify whether $\langle F(\psi), \phi_N \rangle$ is positive (which is required for solution (47)) it suffices to show that $D_N > 0$. The first case, when $D_N = c_N \int_0^\infty g(\xi) e^{3\gamma} d\xi$ follows from the
properties of the bounding region used in theorem 1, which guarantees that $0 \leq U^*(\xi) < \pi/2$, hence $g(\xi) > 0$, combined with $c_n > 0$ for every $n \geq 0$ we get the result. In the second case the result follows from the sign of the integrand in
\[
\frac{2k(d + k - 2)h^3}{3c_N^2} \epsilon^{-3\nu} \int_0^\infty \phi_N(y)^d y d^\tau > 0.
\]
and from $c_N > 0$.

**Note on stability of type II solutions**

In this section we address two concerns that arose earlier in the text. The first one is an ex post validation of our assumption (38) about the dominance of $a_N$ over other coefficients $a_n$. The other issue is the stability of $f_N$. It appears that $f_N$ is unstable, because there is always a negative eigenvalue $\lambda_0 = -\gamma/2$. To obtain any of the constructed solutions we will have to suppress this instability by fine tuning of initial data.

With an estimate on the nonlinear term $\langle F(\psi), \phi_n \rangle$, we can actually solve equations (34) for $a_n$. By plugging (44) into (34) we get linear nonhomogeneous equations
\[
a_n = -\lambda_n a_n + D_n \epsilon^{\gamma+\delta}, \quad n \neq N
\]
which can be explicitly solved by
\[
a_n(s) = a_n(0) e^{-\lambda_n s} + D_n \int_0^s \epsilon(q) \gamma^{\gamma+\delta} e^{-\lambda_n (s-q)} dq.
\]
(56)
The free parameters $a_n(0)$ are connected to initial data via
\[
a_n(0) = \langle \psi, \phi_n \rangle|_{s=0}.
\]
(57)

Let us start with the coefficients in front of higher eigenfunctions, i.e. $n > N$. It is enough to study the limit
\[
\lim_{s \to \infty} \frac{a_n(s)}{a_N(s)} = \frac{c_N}{h} \lim_{s \to \infty} \frac{\epsilon(s)^\delta}{\epsilon(s)/\epsilon(s) + \lambda_n}
\]
\[
= \frac{c_N}{h} \lim_{s \to \infty} \frac{\epsilon(s)^\delta}{\lambda_n - \lambda_N} = 0.
\]
Hence, without any assumptions on $a_n(0)$ we have $|a_N(s)| \gg |a_n(s)|$ for $n > N$.

For $n < N$, let us rewrite (56) as
\[
a_n(s) = (a_n(0) + D_n \int_0^\infty \epsilon(q)^{\gamma+\delta} e^{\lambda_n q} dq) e^{-\lambda_n s} - D_n \int_s^\infty \epsilon(q)^{\gamma+\delta} e^{-\lambda_n (s-q)} dq.
\]
(58)

With elementary calculations and knowledge of $\epsilon$ one can show that the integrals in (58) converge if $n < N$. The second term in (58) is actually much smaller than $a_N(s)$. This is evident when we apply l’Hôpital’s rule to get
\[
\lim_{s \to \infty} \frac{a_n(s)}{a_N(s)} = \frac{c_N}{h} \lim_{s \to \infty} \frac{-\epsilon(s)^\delta}{\epsilon(s)/\epsilon(s) + \lambda_n}
\]
\[
= \frac{c_N}{h} \lim_{s \to \infty} \frac{-\epsilon(s)^\delta}{\lambda_n - \lambda_N} = 0.
\]
Hence, without any assumptions on $a_n(0)$ we have $|a_N(s)| \gg |a_n(s)|$ for $n > N$. For $n < N$, let us rewrite (56) as
\[
a_n(s) = \left( a_n(0) + D_n \int_0^\infty \epsilon(q)^{\gamma+\delta} e^{\lambda_n q} dq \right) e^{-\lambda_n s} - D_n \int_s^\infty \epsilon(q)^{\gamma+\delta} e^{-\lambda_n (s-q)} dq.
\]
(58)
We continue with the help of matching condition \( c_N a_N(s) = -h \epsilon(s)^γ \) and equation (45) for \( ε \) to obtain

\[
\frac{c_N}{h} \lim_{s \to \infty} \frac{\epsilon(s)^γ}{(\lambda_n - \lambda_N) - D_{NCN} \epsilon(s)^γ/h} = 0.
\]

In a similar way we can check that for \( n < N \) the first term, containing \( e^{-\lambda_N s} \), is actually much larger than \( a_N(s) \). So if we want \( |a_N(s)| \geq |a_n(s)| \) to hold, the coefficient in front of \( e^{-\lambda_N s} \) in (58) has to be zero. This can be accomplished by selecting particular initial data for which

\[
\langle \psi |_s = 0, \phi_n \rangle = a_n(0) = -D_n \int_0^\infty \epsilon(q)^{γ+δ} e^{δq} dq \quad 0 \leq n < N.
\]

If the initial data, \( \psi |_s = 0 \), fulfills the condition (59) the assumption \( |a_N(s)| \geq |a_n(s)| \) does not lead to a contradiction.

The condition (59) for the solution \( f_N \) imposes \( N \) constraints on the initial data. Each constraint corresponds to one unstable direction along which our solution can diverge from the ansatz \( f_N \). There is, however, one free parameter—the blow-up time \( T \)—that we can use to change the values of coefficients \( a_n(0) \). Any small change \( T \to T + \eta \) in blow-up time results in a small change of self-similar coordinates (15) \( y \to y - \frac{1}{2} \eta \epsilon y + O(\epsilon^2 \eta^2) \) and \( s \to s - \eta + O(\epsilon^2 \eta^2) \). This change in self-similar coordinates affects the initial data \( \psi |_s = 0 \) so the coefficients \( a_n(0) \) also change. In particular, the zeroth coefficient becomes

\[
a_0(0) \to a_0(0) - \eta \left( \partial_s \psi + \frac{γ}{2} \partial_y \psi, \ phi_0 \right) |_s = 0 + O(\eta^γ).
\]

It should be possible to choose a blow-up time \( T \) in such way, that the new \( a_0(0) \) fulfills the condition (59). This mechanism removes one of the constraints on initial data so \( f_N \) has effectively \( N-1 \) unstable directions.

Discussion of the results

In the previous section we analysed the stability of \( f_N \) concluding that the solution \( f_N \) has \( N-1 \) unstable directions. On the other hand, \( N \) is constrained by the condition \( \lambda_N \geq 0 \), or equivalently,

\[
N \geq \frac{1}{4} (d - 2 - \omega) = \frac{1}{4} (d - 2 - \sqrt{(d - 2(k+1))^2 - 8k^2})
\]

with \( d > 2 + k(2 + 2\sqrt{2}) \). The right hand side of the inequality (60) depends on \( k \) and \( d \) and puts a lower bound on the possible \( N \). In turn, the lower bound on \( N \) induces a condition on the existence of stable \( f_N \) for a given \( k \). If we take arbitrary \( k \geq 1 \) and \( d > 2 + k(2 + 2\sqrt{2}) \) we can derive a lower bound on \( N \)

\[
N \geq \frac{1}{4} (d - 2 - \omega) = \frac{1}{4} (d - 2 - \sqrt{(d - 2(k+1))^2 - 8k^2}) > \frac{k}{2},
\]

so the instability of solutions \( f_N \) increases with topological degree \( k \).

Only a solution with \( N = 1 \) can be stable, so from the bound \( N > \frac{k}{2} \) we infer that for \( k \geq 2 \) there are no stable solutions \( f_N \). Still, the solutions to (5) are guaranteed to blow up for large class of initial data. Numerical evidence suggests, that the generic blow-up is self-similar, so there has to exist at least one self-similar solution to (5) for \( k \geq 2 \). However, to the authors knowledge, in the literature there are no rigorous results concerning these solutions.

Because (61) is only a lower bound, one can ask if there are any examples of stable solutions. Stable solutions could exist only for 1-corotational maps, so let us assume that \( k = 1 \). The lower bound on \( d \) then becomes \( d > 2 + k(2 + 2\sqrt{2}) = 4 + 2\sqrt{2} \approx 6.828 \ldots \), but because dimension \( d \) is an integer we arrive at \( d \geq 7 \). The first eigenvalue \( \lambda_1 = -\frac{1}{2} + 1 \), which
The predicted blow-up rate for 1-corotational maps is

\[
R(t) = (T - t)^{\frac{1}{2} + \beta_1}
\]

with

\[
\beta_1 = -\frac{1}{2} + \frac{2}{d - 2 - \omega}
\]

and \(\omega = \sqrt{d^2 - 8d + 8}\). The figure depicts the comparison between the predicted value of \(\beta_1\) and \(\beta_1\) obtained from numerical experiment via a relation between \(\frac{\partial u(r, t)}{\partial r}\) and \(t \to T\). In each case the initial data was \(u(r, 0) = r\).

corresponds to the stable solution, is actually positive for all \(d \geq 7\) so in this case there exists a stable solution \(f_1\). In fact, numerical evidence suggests, that \(f_1\) corresponds to a generic blow-up in dimensions \(d \geq 7\).

Existence of a generic type I solution in a form of \(f_1\) can be confirmed numerically, although solutions with finite-time singularities present several conceptual difficulties when solved on a computer. The most significant problem comes from the spatial resolution needed to resolve the shrinking scale of the boundary layer. We overcome this difficulty by employing a well established numerical method called a moving mesh, in which a constant number of mesh points is distributed dynamically to satisfy demands for high mesh density near the singularity, and outside of it. In particular, we modified [2] an existing implementation [15] of moving mesh algorithm MOVCOL [17]. For an in-depth description of an application of MOVCOL to solutions with finite time singularity we refer the reader to a paper on a type II blow-up for chemotaxis aggregation by Budd et al [5].

For \(d \geq 8\) the generic blow-up rate is given by

\[
R(t) = C_v \epsilon_0 (T - t)^{\frac{1}{2} + \beta_1}, \quad \beta_1 = -\frac{1}{2} + \frac{2}{d - 2 - \omega}, \quad \omega = \sqrt{d^2 - 8d + 8}. \tag{62}
\]

By definition (8) \(R(t)\) is inversely proportional to \(\sup_{r \geq 0} |\partial_r u(r, t)|\), which can be easily obtained from numerical experiments. In fact, for \(k = 1\) the supremum is always attained at the point \(r = 0\), so we can replace \(\sup_{r \geq 0} |\partial_r u(r, t)|\) with \(|\partial_r u(0, t)|\). To verify the blow-up rate we study the ratio

\[
\frac{\partial_r u(0, t)}{\partial_r u(0, t)} = -\frac{R'(t)}{R(t)},
\]

which in \(d \geq 8\) should tend to

\[
\frac{\partial_r u(0, t)}{\partial_r u(0, t)} \to \left(\frac{1}{2} + \beta_1\right) \quad \text{as } t \to T.
\]

We compare \(\beta_1\) obtained from numerical experiments with its theoretical value in figure 3. An additional test compares the shape of a numerical solution near the origin with the shape of
For $d = 7$ it holds $\sqrt{T - t} \frac{\partial_t u(0, t)}{\partial u(0, t)} = C \left( -\log(T - t) - s_0 \right)$, asymptotically as $t \nearrow T$, with $C$ independent of initial data. In this table we compare values of $C$ and $s_0$ obtained from fitting the asymptotic relation to the numerical solution for various initial data. The values of $C$ indeed don’t change significantly among the tested initial data.

| Initial data | $T$   | $C$   | $s_0$  |
|--------------|-------|-------|--------|
| $r$          | 0.22913 | 0.22512 | -0.43646 |
| $r + \sin(r)$ | 0.066835 | 0.22475 | 0.45864 |
| $r - \sin(r)$ | 0.44672 | 0.22500 | -0.11921 |

A more challenging numerical test is to verify the blow-up rate in dimension $d = 7$. We expect (see equation (9)) the blow-up rate $R(t) = \frac{C}{\sqrt{T - t}} \left( -\log(T - t) - s_0 \right)$, with only $s_0$ depending on initial data. To verify that the blow-up rate agrees with numerical solution we study the quantity $\sqrt{T - t} R(t)$, which should be a linear function of $-\log(T - t)$ with slope independent on initial data. On the other hand, the shift $-Cs_0$, should vary with initial data. In the picture we present results for initial data $u(r, 0) = r$ and $u(r, 0) = r \pm \sin(r)$, each with its own blow-up time $T$. The particular values of blow-up time, slope and shift are shown in table 1. The blow-up rate $R(t)$ is given by $\frac{\partial_t u(0, t)}{\partial u(0, t)}$.

The function $f_1$ with its respective inner and outer solutions as in figure 2. This plot captures a solution at time $T - t \approx 10^{-5.5}$.

A more challenging numerical test is to verify the blow-up rate in dimension $d = 7$. We expect (see equation (9)) the blow-up rate

$$R(t) = \frac{C \sqrt{T - t}}{-\log(T - t) - s_0}, \quad C = \left( \frac{h \gamma}{c_1 D_1} \right) \frac{1}{\sup_{|\xi| \geq 0} \left| \frac{\partial_t u}{\partial u}(\xi) \right|}.$$ 

This scenario is significantly more difficult to verify than (62) because in order to see the logarithmic correction we must get much closer to the blow-up time $T$. At the same time, the choice of initial data should only influence the constant $s_0$, but not $C$. We start with the relation $\frac{\partial_t u(0, t)}{\partial u(0, t)} = 1/R(t)$, by which we get

$$\sqrt{T - t} \frac{\partial_t u(0, t)}{\partial u(0, t)} = C \left( -\log(T - t) - s_0 \right). \quad (63)$$

To test our conjectured blow-up rate we plot the left hand side of (63) against $-\log(T - t)$, expecting to see a linear function after sufficiently long time. The experimental values of $C$, $T$ and $s_0$ are displayed in table 1, while the relation (63) is depicted in figure 4.

Appendix

Existence and asymptotic form of harmonic maps

Theorem 1. For \( d > 2 + k(2 + 2\sqrt{2}) \), a solution \( v(x) \) to equation

\[
v''(x) + (d - 2)v'(x) + k(d + k - 2) \sin(v) = 0
\]

subjected to boundary conditions

\[
v(x) = -\pi + 2e^{-kx} + O(e^{-3kx}), \quad \text{for} \quad x \to -\infty.
\]

exists and has an asymptotic

\[
v(x) = h_+ e^{-\gamma x}(1 + O(e^{-2x}) + O(e^{-\omega x})), \quad \text{for} \quad x \to +\infty,
\]

where \( h_+ \) is a strictly negative constant, while \( \gamma \) and \( \omega \) are defined in (25).

Proof. The proof bases on the analysis of a phase portrait spanned by \((v, v')\) of autonomous equation (64) and consists of three steps.

Construction of no-escape region: Let us start by defining the vector field

\[
F(v, v') = (v', -(d - 2)v' - k(d + k - 2) \sin(v)).
\]

We are interested in a heteroclinic orbit connecting two critical points of \( F \), starting at \((-\pi, 0)\) and ending at \((0, 0)\). We construct a trapping region \( S = \{(v, v') \mid -k \sin(v) \leq v' \leq -\gamma \sin(v), -\pi < v < 0\} \), which includes critical points \((-\pi, 0)\) and \((0, 0)\). No integral curve of \( F \) starting in \( S \) can leave \( S \) (see figure 1).

Indeed, if we define \( n(v) = (-k \cos(v), 1) \) as a normal vector to a curve \( v' = -k \sin(v) \), pointing inward of \( S \), by a direct computation we get

\[
F(v, -k \sin(v)) \cdot n(v) = -k^2 \sin(v)(1 - \cos(v)),
\]

which is positive for \(-\pi < v < 0\). Similarly, taking a normal vector \( \pi(v) = (-\gamma \cos(v), -1) \) (again directed inward \( S \)) to a curve \( v' = -\gamma \sin(v) \) gives

\[
F(v, -\gamma \sin(v)) \cdot \pi(v) = -\gamma^2 \sin(v)(1 - \cos(v)),
\]

which is also positive for \(-\pi < v < 0\). Therefore, the vector field \( F \) points inwards on the whole boundary of \( S \) (excluding the stationary points \((0, 0)\) and \((-\pi, 0)\)). This implies that any integral curve of \( F \) starting inside \( S \) must stay in \( S \).

Asymptotic of solutions starting in \( S \): There are two stationary points in \( S \) where a solution can end up. The first one, \((-\pi, 0)\), can be ruled out because inside \( S \) vector field \( F \) has a nonzero horizontal component pointing to the right. The remaining stationary point, \((0, 0)\), gives a general asymptotic for of \( v \) as

\[
v(x) = 2h_+ \cdot e^{\mu_+ x}(1 + O(e^{-2x})) + 2h_- \cdot e^{\mu_- x}(1 + O(e^{-2x}))
\]

where \( \mu_{\pm} < 0 \) are eigenvalues of \( \nabla F(0, 0) \)

\[
\mu_+ = -\gamma, \quad \mu_- = -\gamma - \omega.
\]
At this point, $h_-$ and $h_+$ are constants depending on initial data and there are no restrictions on their values. Because $(v, v') \in S$, we have $v' < -\gamma \sin(v) < -\gamma v$. If we combine the latter inequality with the asymptotic form of $v$, we get

$$-\omega h_- \cdot (1 + O(e^{-2x})) < 0. \quad (67)$$

On the other hand, from $v < 0$ we know that $h_- \cdot (1 + O(e^{-2x})) < 0$. This contradicts with $\omega > 0$, so $h_+ \neq 0$. We can again use $v < 0$, this time with leading order term proportional to $h_+$, to get $h_+ < 0$.

**Boundary conditions in the thesis guarantee $(v, v') \in S$:** When $x \to -\infty$ the solution $v$ with initial conditions $v(x) = -\pi + 2e^{kx} + O(e^{3kx})$ can be expanded as a Taylor series in $e^x$ in a following way

$$v(x) = -\pi + 2e^{kx} - \frac{2(d + k - 2)}{3(d + 4k - 2)} e^{3kx} + O(e^{5kx}).$$

It is a matter of routine computation to show that for sufficiently small $x$ we have

$$-k \sin(v(x)) < v'(x) < -\gamma \sin(v(x)). \quad (68)$$

So $(v, v') \in S$ and $v$ has an asymptotic form of (65) with $h_+ < 0$. □
