In bacterial pathogenesis, monitoring and adapting to the dynamically changing environment in the host and an ability to disrupt host immune responses are critical. The virulence determinants of pathogenic bacteria include the sensor/signaling proteins of the serine/threonine protein kinase (STPK) family that have a dual role of sensing the environment and subverting specific host defense processes. STPKs can sense a wide range of signals and coordinate multiple cellular processes to mount an appropriate response. Here, we review some of the well studied bacterial STPKs that are essential virulence factors and that modify global host responses during infection.

Successful adaptation to a changing environment requires efficient monitoring and a rapid response. The cascade of chemical reactions culminate in gene transcription and a fast metabolic adaptation. These rapid changes are important especially when responses have to be orchestrated from different cellular compartments. Thus, given the importance of signaling in the normal functioning of the host cell, it is not surprising that pathogens exploit host cell signaling networks to optimize their infectious cycles. Signaling systems are commonly involved in regulation of the expression of virulence factors of pathogenic bacteria during disease progression. Previously, the two-component systems were the only tools known for environmental sensing in bacteria (1, 2). In contrast, signaling in eukaryotes is accomplished primarily by a network of protein phosphorylation cascades that require the coordinated action of a number of serine/threonine and tyrosine kinases and their associated phosphatases. These protein kinases transfer a phosphate group from ATP or GTP onto specific serine, threonine, and/or tyrosine residues of a protein substrate. Typically, the phosphorylation functionally activates the substrate for catalysis. The structural conservation of the catalytic domain between the two kinases is remarkable and is maintained across kingdoms.

The discovery of eukaryote-like signaling systems in bacterial pathogens has sparked an interest in understanding their function. This is due partly to the fact that eukaryotic protein kinases are currently the largest group of drug targets, second only to G-protein-coupled receptors (25, 26). A large number of STPK inhibitors have been approved by the Food and Drug Administration for use in humans (26), and ~150 kinase inhibitors are also being tested in clinical trials (27, 28). In addition, STPKs are also being investigated as potential tools in therapeutic strategies (29, 30). Therefore, studies on prokaryotic STPKs in human pathogens have gained interest owing to the prospect of exploiting these signaling components in future anti-infective therapies.

The contribution of STPKs to bacterial growth and pathogenesis is multifaceted, as has been observed for other signaling systems. However, the mechanisms by which these kinases mediate diverse functions in a coordinated fashion remain to be completely understood, particularly their role(s) during host invasion/persistence, as we propose to detail in this minireview. The STPK-directed host-pathogen interactions known so far appear to be of different types: those in which the bacterial STPK phosphorylates a host substrate(s), those in which host defense is disrupted by STPK activity, and those in which the role of STPK is essential but the mechanism of interaction has not yet been clarified.

**Bacterial Ser/Thr Kinases That Phosphorylate Eukaryotic Host Proteins**

*Yersinia YpkA*—Bacteria from the genus *Yersinia* (*Y. pestis, Y. pseudotuberculosis,* and *Y. enterocolitica*) secrete the STPK *Yersinia* protein kinase A (YpkA, also named YopO) into host target cells via a type III secretion system (T3SS) (31). This kinase has been shown to disrupt the actin cytoskeleton and contribute to resisting phagocytosis by macrophages (32, 33). YpkA is a multidomain protein harboring an N-terminal Ser/Thr kinase domain and a C-terminal guanine nucleotide dissociation inhibitor (GDI) domain, followed by an actin-binding domain (Fig. 1A) (14, 15, 32, 34, 35). Once secreted into the host, YpkA localizes at the inner surface of the cytoplasmic membrane in eukaryotic cells (15, 34). Its kinase domain seems essential for virulence, as strains harboring an internal deletion in this domain show reduced lethality in infected mice (14, 36).

**FIGURE 1.** *Y. pestis* YpkA phosphorylates a host substrate and interferes with the host RhoA/Rac pathway. A, YpkA is a multidomain protein harboring an STPK domain, a GDI domain, and an actin-binding domain (ABD). aa, amino acids. B, in an inactive form, the heterotrimeric G-protein (Gαq/βγ) is associated with G-protein-coupled receptors (R), with Gαq bound to GDP. Upon activation of the receptor, GDP is exchanged for GTP on Gαq, which induces dissociation of the trimer from the receptor, and into Gαq and Gβγ subunits. Gαq-GTP activates the RhoA/Rac pathway through the LARG Rho guanine nucleotide exchange factor (leukemia-associated RhoGEF), which triggers formation of actin stress fibers. The GTPase activity of Gαq, then hydrolyzes GTP to GDP, and the system reverts to the inactivate state. C, when YpkA is secreted into the host cell, its STPK domain is activated through interaction with host actin, and it phosphorylates Gαq. The latter can no longer bind GTP, which eventually leads to disruption of cytoskeletal integrity. Concurrently, the GDI domain of YpkA interacts with RhoA and Rac, leading to a switch off of the RhoA/Rac pathways.

In *vitro* kinase activity has been demonstrated for YpkA as being dependent on its interaction with globular actin (32, 37). Moreover, using J774 macrophage cells extract, Juris *et al.* (38) have shown that YpkA phosphorylates actin and otubain, a cysteine protease involved in ubiquitin signaling and in the macrophage activation cascade, although the regulatory role of phosphorylation in these interactions was not clearly demonstrated. Although the relation between YpkA and actin depolymerization remains to be clarified, it seems that the kinase activity of YpkA is necessary for host cell shape and phagocytosis inhibition (36, 37).

The Gαq family of heterotrimeric G-proteins is known to activate RhoA-mediated pathways and plays a central regulatory role in a number of cellular activities requiring cytoskeletal rearrangements such as phagocytosis and motility (Fig. 1B) (39). Navarro *et al.* (40) demonstrated that YpkA phosphorylates Gαq on Ser-47, a key residue located in the binding loop of the G-protein, inhibiting GTP binding and thereby inhibiting Gαq signal transduction (Fig. 1C). Moreover, YpkA has also been shown to interact with other host proteins without phosphorylating them. The YpkA kinase carries a C-terminal Rho GTPase-binding domain that specifically binds and inactivates the small GTPases RhoA and Rac-1, two proteins of the Rho family involved in cytoskeleton integrity (34, 35, 41). YpkA thus mimics a host GDI (35) to “switch off” the RhoA/Rac pathways, causing cytoskeletal disruption and distortion of cell shape. Thus, the kinase- and GTPase-binding domains of YpkA act synergistically to impair specific host cellular functions. These studies highlight the role of YpkA in promoting the immune system failure at various levels.

*Staphylococcus Stk1*—*S. aureus* is considered mostly as an extracellular pathogen, but it can invade a variety of mammalian non-professional phagocytes such as epithelial cells (42) and keratinocytes (43) and survive phagocytosis by professional phagocytes such as neutrophils (44) and macrophages (45). *S. aureus* displays various protective and offensive responses that facilitate its persistence in the host (46, 47). Interestingly, Stk1 (also named PknB) has been shown to be important for infection in mice in an abscess model (48) as well as in a cutaneous model (49), and it is also required for antibiotic resistance (49). Stk1 was thought to be strictly membrane-associated until Miller *et al.* (50) demonstrated that the full-length protein could be detected in the extracellular medium, although the mechanism remains unknown. In this elegant study, the authors used a peptide microarray loaded with human peptides and identified 68 potential host-phosphorylated substrates...
Bacterial STPKs That Disrupt Host NF-κB Pathways

In a host cell, the transcription factor NF-κB protein complex is critically important in triggering an immune/inflammatory response. In the absence of cognate stimuli, NF-κB is prevented from translocating to the nucleus by inhibitors of the IκB family. In response to stimuli such as a bacterial infection, NF-κB is translocated to the nucleus, where it transcriptionally induces specific genes involved in a variety of processes aimed at eliminating the pathogen. In contrast, certain pathogenic bacteria present mechanisms to counter these attacks, some of which involve bacterial STPKs. Structurally, the different members of the NF-κB family are composed of combinations of five subunits, p50, p52, RelA (p65), RelB, and c-Rel, of which p50 and p52 are derived from p105 and p100, respectively. STPKs from different pathogenic bacteria seem to interact with host factors to disrupt the NF-κB signaling pathways and downstream processes as discussed below (Fig. 2).

Legionella LegK1—Legionella pneumophila infects the lung macrophages and causes the so-called Legionnaires’ disease. Once in the phagosome, this pathogen is able to redirect the classical bacterial phagolysosomal elimination to establish a replicative niche within an endoplasmic reticulum-derived compartment, named the Legionella-containing vacuole, and evade host cell defenses (57–59).

Different species of Legionella harbor three to five genes encoding putative STPKs (legk1–legk3 for L. pneumophila Philadelphia-1 (60) and legk1–legk5 for L. pneumophila Lens (61)). LegK1–LegK4 are known to be secreted by a type IV secretion system called Dot/Icm, which is essential for intracellular growth (58, 59). Only LegK1 has been shown to interfere with the NF-κB pathway, acting as an inflammatory activator. Using an NF-κB-specific luciferase reporter system, Ge et al. (62) demonstrated that ectopic expression of LegK1 in HEK-293T cells triggers activation of the NF-κB cascade (Fig. 2, A (left) and B). The same assay conducted with LegK2, LegK3, and a LegK1 kinase-dead mutant (carrying a mutation in the kinase domain) resulted in no activation of the NF-κB system. Therefore, LegK1 seems to be the only STPK able to interfere with the NF-κB pathway, and its kinase activity is required. Moreover, LegK1 activity is specific to NF-κB and does not affect other innate immune signaling pathways such as MAPK and IFN (62). Moreover, in the same study, the authors used a cell-free reconstitution system to show that LegK1 is able to phosphorylate IκBα, a central regulator of the NF-κB pathway (Fig. 2A), on Ser-32 and Ser-36 in an IκB kinase (IKK)-independent manner. In vitro assays with IκBα and a variety of LegK1 derivatives confirmed phosphorylation of IκBα by LegK1, indicating that the N-terminal “pre-kinase” part is critical for IκBα phosphorylation. The authors also demonstrated that p100, the precursor of the non-canonical NF-κB complex, is processed into p52 when phosphorylated by LegK1 (Fig. 2B). Taken together, these data highlight the function of the LegK1 kinase as a mimic of the host IKKs in the NF-κB response activation. Thus, L. pneumophila LegK1 is a STPK that phosphorylates host substrates (IκBα and p100) and disrupts the NF-κB pathway, thereby modulating host innate defenses and inflammatory responses during infection.

Shigella OspG—Shigella spp. are the agents of shigellosis in humans, a disease that is characterized by the destruction of the colonic epithelium and that is responsible for 1 million deaths per year (63). Shigella spp. use a T3SS to enter epithelial cells, thus triggering apoptosis (64). About 20 proteins have been identified as substrates of the T3SS (65). One of these, OspG, is an STPK known to manipulate the host innate immune system by down-regulating the canonical NF-κB pathway (Fig. 2A right). Using in vivo and in vitro approaches, Kim et al. (66) demonstrated that OspG is an STPK able to bind to ubiquitinylated E2 enzymes such as UbcH7 and UbcH5 without phosphorylating them. They showed that this sequestration leads to a decrease in IκBα degradation, thus blocking the activation pathway of NF-κB. The action of OspG seems to be dependent on its kinase activity, as the inactivated kinase mutant does not generate a similar attenuation of NF-κB signaling. In addition,
interference with the host NF-κB signaling pathways by STPKs of pathogenic bacteria: LegK1, OspG, and NleH1. In the canonical NF-κB pathway, in response to stimulation, the IKK trimer (IKKα/IKKβ/NEMO) phosphorylates IκBα, which normally sequesters the NF-κB (p50/p65) dimer in the cytoplasm. Once phosphorylated, IκBα dissociates from NF-κB dimer, which then translocates into the nucleus and activates genes implicated in the immune response. The dissociated phospho-IκBα is ubiquitinated by the ubiquitylation system (E1, E2, and E3) and is addressed to and degraded in the proteasome. In the non-canonical pathway, the IKKα dimer phosphorylates p100, the precursor of p52 that is an inhibitor of the NF-κB dimer. Once phosphorylated, p100 is processed to p52, and the p52/RelB NF-κB dimer thus activated is translocated into the nucleus. The Legionella STPK LegK1 mimics IKKs in both canonical (A, left) and non-canonical (B) pathways and induces activation of the NF-κB pathways in the host. A (right), the Shigella sp. STPK OspG interacts with the ubiquitin-conjugating enzyme E2, blocking phospho-IκBα degradation and thus silencing the inflammatory response of the host. C, the RPS3 protein interacts with the p65 subunit of NF-κB, and when phosphorylated by IKKα, RPS3 is translocated into the nucleus and determines the regulatory specificity of NF-κB for target genes. The E. coli STPK NleH1 inhibits RPS3 phosphorylation and thus inhibits the host NF-κB response mechanism. CRKL could be involved in this inhibition, but the exact mechanism remains to be elucidated.

**Bacterial STPKs with Unidentified Host Substrates**

In some of the host-pathogen interactions known so far, the kinase activity of the bacterial STPKs is required, but the substrate has not been identified. In addition to *E. coli* NleH1 and NleH2 described above, this category also includes *Legionella* LegK2. Similarly, the substrates of most of the mycobacterial STPKs that participate in host-pathogen interactions have not yet been identified.

**Legionella LegK2**—LegK2 has been identified to be involved in the virulence of *L. pneumophila* by a combination of *in vitro* and *in vivo* approaches (61). A ΔlegK2 mutant showed no defects in *in vitro* growth but presented less cytotoxicity and delayed intracellular replication in amoebas compared with the wild-type strains. Moreover, vacuoles containing the mutant strain showed less efficient recruitment of endoplasmic reticulum markers. Complementation assays performed with wild-

**Escherichia NleH1 and NleH2**—Enteropathogenic *Escherichia coli* (EPEC) and enterohemorrhagic *E. coli* (EHEC) are two diarrheagenic strains of *E. coli* that contribute to the health burden of food-borne disease. EHEC and EPEC are known to express and secrete effectors into intestinal epithelial cells through a T3SS (68). NleH1 and NleH2 have been biochemically characterized as STPKs and secreted in HeLa cells through a T3SS. These STPKs are able to interact with RPS3, a host protein known to bind the p65 subunit of NF-κB and regulate its affinity for its target genes (Fig. 2C) (69, 70). The interaction of RPS3 with NleH1 and NleH2, but not NleH2, reduces the nuclear abundance of RPS3, causing inhibition of the NF-κB-dependent transcriptional activity. The NF-κB activity seems also to be decreased by NleH2 when IKKβ is overexpressed (71, 72). In *in vivo* tests showed that the EHEC ΔnleH1 strain, but not the ΔnleH2 strain, is hypervirulent in a gnotobiotic piglet infection model, indicating that NleH1 and NleH2 differentially regulate the inflammatory response of the host (70). In a mouse intestine model, EPEC NleH1 and NleH2 seemed to increase colonization and decrease inflammation (71). Phosphorylation of RPS3 on Ser-209 by IKKβ enhances its association with importin-α, thus mediating RPS3 entry into the karyopherin pathway for nuclear translocation (73). The interaction of RPS3 with NleH1 leads to the inhibition of its phosphorylation by IKKβ. Recently, a high-throughput screen to identify a host cell substrate of NleH1 yielded the CRKL (v-Crk sarcoma virus CT10 oncogene-like) protein (74). According to the proposed model, CRKL interacts dually with NleH1 and IKKβ. Interaction of a kinase-active form of NleH1 with CRKL is essential for the ability of NleH1 to inhibit RPS3 phosphorylation by IKKβ.

**FIGURE 2.** Interference with the host NF-κB signaling pathways by STPKs of pathogenic bacteria: LegK1, OspG, and NleH1. In the canonical NF-κB pathway, in response to stimulation, the IKK trimer (IKKα/IKKβ/NEMO) phosphorylates IκBα, which normally sequesters the NF-κB (p50/p65) dimer in the cytoplasm. Once phosphorylated, IκBα dissociates from NF-κB dimer, which then translocates into the nucleus and activates genes implicated in the immune response. The dissociated phospho-IκBα is ubiquitinated by the ubiquitylation system (E1, E2, and E3) and is addressed to and degraded in the proteasome. In the non-canonical pathway, the IKKα dimer phosphorylates p100, the precursor of p52 that is an inhibitor of the NF-κB dimer. Once phosphorylated, p100 is processed to p52, and the p52/RelB NF-κB dimer thus activated is translocated into the nucleus. The Legionella STPK LegK1 mimics IKKs in both canonical (A, left) and non-canonical (B) pathways and induces activation of the NF-κB pathways in the host. A (right), the Shigella sp. STPK OspG interacts with the ubiquitin-conjugating enzyme E2, blocking phospho-IκBα degradation and thus silencing the inflammatory response of the host. C, the RPS3 protein interacts with the p65 subunit of NF-κB, and when phosphorylated by IKKα, RPS3 is translocated into the nucleus and determines the regulatory specificity of NF-κB for target genes. The E. coli STPK NleH1 inhibits RPS3 phosphorylation and thus inhibits the host NF-κB response mechanism. CRKL could be involved in this inhibition, but the exact mechanism remains to be elucidated.

type and kinase-dead proteins provided evidence that LegK2 kinase activity is required for the normal infectious phenotype of *L. pneumophila* (61). Although no host targets have yet been identified, LegK2 seems to be a crucial virulence determinant involved in the establishment of the replicative niche in the macrophage.

*Mycobacterium tuberculosis* STPKs—*M. tuberculosis* is the causative agent of tuberculosis. It is capable of infection and long-term survival in host macrophages. The bacteria possess several virulence factors that are expressed at different steps of infection all the way to establishing a latent infection and an eventual resuscitation from dormancy. Genome sequence analyses revealed 11 STPKs (8), four of which have been demonstrated to be involved in virulence in *vivo*: PknH, PknI, PknK, and PknG. Although these STPKs are important virulence factors, their host cell interactors have not yet been identified, except for that of PknG. Studies with genetic mutants of the above STPKs have revealed their roles in establishing an infection. In a mouse model, the *pknH* mutant was found to survive and replicate to a higher bacillary load in mouse organs compared with its parental strain (75). Similarly, a *pknI*-null mutant showed increased intracellular growth inside THP-1 macrophage cells and hypervirulence in immunodeficient mice (76). More recently, Malhotra et al. (77) showed that a *pknK* deletion resulted in increased resistance of the mutant to acidic pH, hypoxia, and oxidative and stationary phase stress in *vitro* and increased survival during persistent infection in mice. Moreover, assays performed on host immune effectors suggested an immunomodulatory function of PknK during acute infection in mice (77).

PknG is a soluble STPK expressed by pathogenic or attenuated mycobacteria such as *M. tuberculosis* and *Mycobacterium bovis* bacillus Calmette-Guérin, but not by *Mycobacterium smegmatis*, a non-pathogenic species. PknG is known to play a role in persistence inside macrophages, presumably by inhibiting the critical step of phagosome-lysosome fusion, as shown for *M. bovis* and *M. smegmatis* in cultured macrophages (78, 79) and in a mouse model (80). Interestingly, the basis for the PknG-mediated enhanced survival in macrophages appears to be its interaction with, but not phosphorylation of, PKCo, an STPK from the host cell that is known to regulate phagolysosome formation (81). Other studies have also highlighted the role of PknG in interacting and disturbing host defense pathways (82–85). Recently, in *Mycobacterium marinum*, SecA2 was identified as the secretion system that likely introduces PknG into the host cell (86).

Conclusions

Thus, the emerging theme from the above examples is not that only are the STPKs in pathogenic bacteria essential for regulating important bacterial processes, but some are secreted such that they can interact with host substrates also, subverting essential host functions such as immune responses and cell shape and integrity. It is not yet clear whether these STPK interactions all involve phosphorylation of a host substrate. In some cases, the phosphorylation of a host substrate has been demonstrated; whereas in others, the STPK kinase activity is seen to be essential, but a phosphorylated substrate has not been identified. The biochemical mechanisms of these pathogen-directed targeted perturbations in the host cell signaling network are being actively investigated. Thus, bacterial STPKs are proving to be molecular switches that play key roles in host-pathogen interactions.
