A subcritical transition to turbulence in magnetized Keplerian shear flows is investigated using a statistical approach. Three-dimensional numerical simulations of the shearing box equations with zero net magnetic flux are employed to determine the transition from decaying to sustained turbulence as a function of the magnetic Reynolds number \( Rm \). The results reveal no clear transition to sustained turbulence as the average lifetime of the transients grows as an exponential function of \( Rm \), in accordance with a type-II supertransient law.

There has been much progress in recent years on the understanding of the nature of subcritical transitions to turbulence in hydrodynamic flows, wherein the laminar state is linearly stable for all Reynolds numbers and finite amplitude perturbations are necessary to drive the system towards a turbulent state. Numerical and experimental works indicate that turbulence in systems like plane–Couette and pipe flows is a transient phenomenon [1, 2], although this is still a disputed topic [3, 4]. Although much has been accomplished for hydrodynamic turbulence in this area, the same cannot be said about magnetohydrodynamic (MHD) turbulence in systems with subcriticality, for which statistical studies are scarce.

A classical problem of subcritical transition to turbulence is provided by accretion disks, where, in the absence of magnetic fields and when shear is the only stratification, Keplerian flows are linearly stable [5]. The rate of mass accretion in the disk depends on the outward transport of angular momentum and one would think that turbulence is the natural candidate for transport. However, both numerical [6, 8] and laboratory [9] experiments have revealed that, if a subcritical hydrodynamic transition to turbulence was to exist in Keplerian flows, then the associated turbulent transport of angular momentum is very weak and unable to match observational constrains.

When a mean vertical field is applied, the magnetorotational instability [10] provides a linear instability that may result in a strong MHD turbulence capable of generating adequate rates of angular momentum transport [11, 12]. If there is no imposed background magnetic field, the original (seed) field can decay with time due to finite resistivity. In that case, some type of nonlinear dynamo process is necessary to amplify and sustain the seed field and, consequently, the instability in zero net flux simulations is nonlinear [13]. Rinçon et al. [14] identified a self-sustaining dynamo solution in a magnetized rotating plane–Couette flow in the Keplerian regime, but the steady solutions were found only in a narrow range of low values of the Reynolds number. Other works have reported the existence of nonlinear dynamos in turbulent MHD regimes [13], yet, little is known about how turbulence evolves as a function of the magnetic Prandtl number \( Pm \) (the ratio of viscosity to resistivity) and whether it can be sustained for long runs or not. Recently, Fromang et al. [15] studied the onset of turbulence in accretion disks using an unstratified shearing box with zero net magnetic flux and found that turbulence disappears when the magnetic Prandtl number falls below a critical value that seems to be a decreasing function of the kinetic Reynolds number. Note, however, that vertical stratification might change this picture [16].

The present letter explores the onset of turbulence in three-dimensional, zero net flux, MHD simulations of Keplerian shear flows as a function of the magnetic Reynolds number \( Rm \). We focus on the statistical aspects of the subcritical transition, which is an approach that has been unexplored in MHD simulations, despite its popularity in the hydrodynamics community. From our results, there seems to be no clear transition to sustained turbulence. Instead, the average lifetime of the turbulence \( \tau \) grows as an exponential function of \( Rm \), following a type-II supertransient law [17].

We solve the shearing box equations [18], which represent the dynamics in a box moving with the disk’s angular velocity \( \Omega(r_0) \), where \( r_0 \) is a fiducial radius that determines the location of the center of the box. In Cartesian coordinates, with \( \phi \to y \) and \( r \to r_0 + x \), the shearing box equations read as

\[
\partial_t \mathbf{v} + \nabla \cdot \mathbf{v} = -\frac{1}{\rho} \nabla P + \frac{1}{\mu_0 \rho} (\nabla \times \mathbf{B}) \times \mathbf{B} - 2\Omega \times \mathbf{v} + 2\Omega \mathbf{s} \mathbf{x} + \nu \nabla^2 \mathbf{v},
\]

\[\partial_t \mathbf{B} = \nabla \times (\mathbf{v} \times \mathbf{B}) + \eta \nabla^2 \mathbf{B},\]
∇ \cdot \mathbf{B} = 0, \quad \nabla \cdot \mathbf{v} = 0, \quad (3)

where \( \Omega = r^{-3/2} \) for a Keplerian disk, \( S = -r \partial_r \Omega = (3/2) \Omega \), \( \eta \) is the magnetic diffusivity, \( \mu_0 \) is the magnetic permeability, \( \rho \) is the gas density, and \( P \) is the pressure. The fluid velocity can be decomposed as \( \mathbf{v} = \mathbf{v}_0 + \mathbf{u} \), where the steady state solution is given by the shear flow \( \mathbf{v}_0 = -S x \hat{y} \) and \( \mathbf{u} \) is the perturbation field. The equations for \( \mathbf{u} \) are solved with the pseudospectral code described by Lesur et al. [8] using shearing sheet boundary conditions [11]. The \( xyz \) aspect ratio employed is \( 1 \times \pi \times 1 \). The kinetic and magnetic Reynolds numbers are defined as \( Re = S d^2 / \nu \) and \( Rm = S d^2 / \eta \), respectively, where \( d \) is the shearwise size of the box. Time is measured in shear time units, \( 1 / \nu \).

Transition to turbulence is investigated by fixing \( Re \) while varying \( Rm \). The value of \( Re \) is taken from Fig. 11 of Fromang et al. [15], where for \( Re = 3125 \) there is a transition to turbulence somewhere between \( Rm = 6250 \) and \( Rm = 12500 \), thus, the magnetic Prandtl number \( Pm = Rm / Re > 1 \). Since we are not interested in the kinematic dynamo regime, the initial growth of a small seed magnetic field is not important to our discussions. Our question is: given a turbulent state, can it be sustained for all time? If not, how long it takes, on average, to decay? The turbulent states are obtained from long runs where the velocity and magnetic fields are initialized with a large-scale random noise (only the four largest modes are nonzero at \( t = 0 \)) with amplitude of the order of 1. After some time, energy spreads to other modes and the random fields settle to a turbulent state. Figure 1 illustrates the typical turbulent patterns found at \( Re = 3125 \) and \( Rm = 11000 \) for the radial component of the velocity (upper panel) and magnetic (lower panel) fields at \( t = 500 \). Since \( Pm > 1 \) and there is no proper large scale dynamo, the characteristic spatial scales in the magnetic fields are smaller than in the velocity fields. The numerical resolution employed is \( 64 \times 128 \times 64 \), which is the same resolution used for this problem in Ref. [15]. The convergence of the code is checked by comparing the time-averaged power spectra obtained with this run with a higher-resolution run (128 \( \times \) 256 \( \times \) 128). The results are shown in Fig. 2, where the solid black line represents the lower-resolution kinetic energy spectrum and the solid red line the lower-resolution magnetic energy spectrum. The higher-resolution spectra are plotted in dashed lines and agree quite well with the lower resolution runs. There is a disagreement in the small scales in the kinetic spectra, but this has a low impact on the global behaviour. Table 1 contains time-averaged values for the kinetic and magnetic energies, as well as for the Reynolds and Maxwell stresses, which are defined, respectively, as \( \alpha_{Rey} = \langle u_x u_y \rangle \) and \( \alpha_{Max} = - \langle B_x B_y \rangle \). The quantities are computed with both resolutions for \( Re = 12500 \). In the remainder of this letter, we adopt the lower resolution. Note that the lack of a properly defined inertial range in the power spectra indicates that the turbulence is not fully developed.

FIG. 1. (Color online) Volume rendering plots of \( u_x \) (a) and \( B_x \) (b) for a turbulent state at \( Re = 3125 \) and \( Rm = 11000 \).

| Res. | 64 \( \times \) 128 \( \times \) 64 | 128 \( \times \) 256 \( \times \) 128 |
|------|----------------------------------|----------------------------------|
| \( \langle E_{kin} \rangle_1 \) | \( 2.11 \times 10^{-3} \) | \( 2.07 \times 10^{-3} \) |
| \( \langle E_{mag} \rangle_1 \) | \( 8.45 \times 10^{-3} \) | \( 8.52 \times 10^{-3} \) |
| \( \langle \alpha_{Rey} \rangle_1 \) | \( 5.22 \times 10^{-4} \) | \( 5.24 \times 10^{-4} \) |
| \( \langle \alpha_{Max} \rangle_1 \) | \( 3.68 \times 10^{-3} \) | \( 3.69 \times 10^{-3} \) |

The turbulence shown in Fig. 4 eventually decays toward the laminar state. The decay time is a function of the initial perturbation and \( Rm \). Figure 3 shows an example of a time series of the magnetic (red) and kinetic (black) energies for \( Re = 3125 \) and \( Rm = 12500 \). After more than 6000 time units the turbulence suddenly decays and the system converges to the laminar state.

The high variability of the turbulence decay times as a function of the initial condition for a given \( Rm \) suggests the presence of a chaotic saddle in the phase space [2, 20]. The role of chaotic saddles in generating chaotic transients in dynamical systems is well known and, as mentioned in previous studies on spatiotemporal systems
the average lifetime of the chaotic transients grows as a function of the fractal dimension of the stable manifold of the chaotic saddle. In order to obtain the average lifetime $\tau(Rm)$ of the turbulent transients we compute $P(t)$, the probability of finding a turbulent state at time $t$. For each value of $Rm$, $P(t)$ is obtained from a set of more than 50 and up to 90 different simulations. Each simulation has a turbulent state as initial condition and the simulation stops when either $t = 1000$ or the laminar state is reached, generating a data set of relaminarization times. The turbulent initial conditions are taken from a long run at $Rm = 13000$. To ensure that the initial conditions represent uncorrelated states, they were selected from the referred long turbulent run with 500 shear–time units apart from each other. Figure 4 shows the logarithm of $P(t)$ as a function of $t$ for $Re = 3125$ and a range of different values of $Rm$. The straight lines are least square fits that represent the relation $P(t, Rm) = \exp[-t/\tau(Rm)]$, which is expected for transients due to chaotic saddles. The values of $1/\tau$ are readily obtained from the slopes of the fitted lines. As $Rm$ increases, the slopes decrease, reflecting longer decay times. The convergence is not very good for the lowest values of $Rm$, probably due to a lower fractal dimension of the stable manifold of the chaotic saddle, which implies that a much higher number of initial conditions would be necessary to obtain better statistics.

A graph of $\tau$ versus $Rm$ is plotted in Fig. 5. The top panel shows the data in linear scales and reveals that the inverse lifetime can be well fitted with an exponential law as a function of $Rm$. The dashed curve is given by $1/\tau = \exp(5.3 - 0.00118 Rm)$. The lower panel shows the same data in log–lin scales. These results indicate that the turbulence lifetime follows a type-II supertransient law as a function of $Rm$. This case, there is no apparent transition to sustained turbulence, and the laminar state is the global attractor. If there were a critical $Rm$ for transition to sustained turbulence via a crisis mechanism, a linear decay of $1/\tau$ with $Rm$ would have been expected. The results for a linear fit using only the last four values of $Rm$ are given by the dotted blue line in Fig. 5(a), which represents $1/\tau = 0.0144 - 1.273 \times 10^{-6} Rm$. This fit provides a critical point $Rm_c \sim 11312$, which is clearly incorrect, since Fig. 6 shows that even at $Rm = 12500$ the turbulence is still decaying.

Note that the high values of $Re$ and $Rm$ shown in this letter are based on the shear rate $S$. If the Reynolds numbers are computed based on the root mean square velocity, one obtains a maximum of $Re \sim 180$ and $Rm \sim 650$. Thus, it has been shown that, at least for intermediate Reynolds numbers and magnetic Prandtl numbers greater than one, MHD turbulence in the incompressible shear layer equations with zero net magnetic flux is not self-sustained. The average decay time $\tau$ follows a type-II supertransient law, with an exponential increase of $\tau$ as a function of the magnetic Reynolds number. This is in accordance with results found for subcritical transitions to turbulence in hydrodynamic flows such as the pipe flow and plane Couette flow, where turbulence seems to
be always transient. Supposing that our conclusions can be extended to realistic values of the Reynolds numbers, this suggests that the transient dynamics is much more relevant to the accretion problem than the final attractor.
