Abstract

We obtain properties of $^{12}\text{C}$ in the $ab\ initio$ no-core nuclear shell-model. The effective Hamiltonians are derived microscopically from the realistic CD-Bonn and the Argonne V8' nucleon-nucleon (NN) potentials as a function of the finite harmonic oscillator basis space. Binding energies, excitation spectra and electromagnetic properties are presented for model spaces up to $5\hbar\Omega$. The favorable comparison with available data is a consequence of the underlying NN interaction rather than a phenomenological fit.

While various methods have been developed to solve the three- and four-nucleon systems with realistic interactions\,[1–4], few approaches are suitable for heavier nuclei at this time. Apart from the coupled cluster method\,[5] applied to closed-shell and near-closed shell nuclei, the Green’s function Monte Carlo method is the only approach for which exact solutions of systems with $A \leq 8$, interacting by realistic potentials, have been obtained\,[4].

For more complex nuclei, treated as systems of nucleons interacting by realistic NN interactions, we apply the no-core shell-model approach\,[6–9]. To date, this $ab\ initio$ method has been successfully applied to solve the three-nucleon as well as the four-nucleon bound-state problem\,[6–8]. Here, we address a vastly more complex system, $^{12}\text{C}$, and present first results for an illustrative set of observables with two realistic NN interactions.

There are several pressing reasons to investigate $^{12}\text{C}$ in a way that preserves as much predictive power as possible. The $^{12}\text{C}$ nucleus plays an important role\,[10] in neutrino studies using liquid scintillator detectors. Also, there has been considerable interest recently in parity-violating electron scattering from $(J^\pi, T) = (0^+, 0)$ targets, like $^{12}\text{C}$, to measure the strangeness content of the nucleon\,[11,12]. For these and many other reasons, there have been multi-$\hbar\Omega$ shell model studies of $^{12}\text{C}$ in the past\,[13–15]. However, unlike our approach, phenomenological effective interactions were used.

We start from the two-body Hamiltonian for the $A$-nucleon system, which depends on the intrinsic coordinates alone, $H_A = T_{rel} + \mathcal{V}$, where $T_{rel}$ is the relative kinetic energy operator and $\mathcal{V}$ is the sum of two-body nuclear and Coulomb interactions, $\mathcal{V} = V_N + V_C$. There is no phenomenological one-body term. We neglect many-body interactions at present. To
facilitate our work, we add an $A$-nucleon Harmonic Oscillator (HO) Hamiltonian acting solely on the center-of-mass (CM), $H_{CM} = T_{CM} + U_{CM}$, where $U_{CM} = \frac{1}{2}A m\Omega^2 \vec{R}^2$, $\vec{r}_i = \frac{1}{A} \sum_{i=1}^{A} \vec{r}_i$, and $m$ is the nucleon mass. The effect of this HO CM Hamiltonian will be subtracted in the final many-body calculation. The Hamiltonian, with a pseudo-dependence on $\Omega$, can be cast into the form

$$H^A_{\Omega} = \sum_{i=1}^{A} h_i + \sum_{i<j=1}^{A} V_{ij} = \sum_{i=1}^{A} \left[ \frac{\vec{p}_i^2}{2m} + \frac{1}{2} m\Omega^2 \vec{r}_i^2 \right] + \sum_{i<j=1}^{A} \left[ V_{ij} - \frac{m\Omega^2}{2A} (\vec{r}_i - \vec{r}_j)^2 \right].$$ (1)

Since we solve the many-body problem in a finite HO model space, the realistic nuclear interaction in (1) will yield pathological results unless we derive a model-space dependent effective Hamiltonian. For this purpose, we adopt approaches presented by Lee and Suzuki [16], Da Providencia and Shakin [17], and Suzuki and Okamoto [18], which yield an Hermitean effective Hamiltonian.

According to Da Providencia and Shakin [17], a unitary transformation of the Hamiltonian $H^A_{\Omega}$, which is able to accommodate the short-range two-body correlations, can be introduced by choosing a two-body, in our case translationally invariant, antihermitian operator $S = \sum_{i<j=1}^{A} S_{ij}$, such that

$$\mathcal{H} = e^{-S} H^A_{\Omega} e^{S}. \quad (2)$$

The transformed Hamiltonian can be expanded in terms of up to $A$-body clusters $\mathcal{H} = \mathcal{H}^{(1)} + \mathcal{H}^{(2)} + \mathcal{H}^{(3)} + \ldots$, where the one-body and two-body pieces are given as $\mathcal{H}^{(1)} = \sum_{i=1}^{A} h_i$, $\mathcal{H}^{(2)} = \sum_{i<j=1}^{A} \tilde{V}_{ij}$, with

$$\tilde{V}_{12} = e^{-S_{12}} (h_1 + h_2 + V_{12}) e^{S_{12}} - (h_1 + h_2). \quad (3)$$

The full space is divided into a model or P-space, and a Q-space, using the projectors $P$ and $Q$ with $P + Q = 1$. It is then possible to determine the transformation operator $S_{12}$ from the decoupling condition

$$Q_2 e^{-S_{12}} (h_1 + h_2 + V_{12}) e^{S_{12}} P_2 = 0. \quad (4)$$

The two-nucleon-state projectors ($P_2, Q_2$) follow from the definitions of the $A$-nucleon projectors $P$, $Q$. This approach has a solution [18], $S_{12} = \arctanh(\omega - \omega^\dagger)$, with the operator $\omega$ satisfying $\omega = Q_2 \omega P_2$. This is the same operator, which we previously employed [9]. It can be directly obtained from the eigensolutions $|k\rangle$ of $h_1 + h_2 + V_{12}$ as $\langle \alpha_P | \omega | \alpha_P \rangle = \sum_{k \in K} \langle \alpha_Q | k \rangle \langle k | \alpha_P \rangle$, where we denote by tilde the inverted matrix of $\langle \alpha_P | k \rangle$. In the above relation, $| \alpha_P \rangle$ and $| \alpha_Q \rangle$ are the 2-particle model-space and Q-space basis states, respectively, and $K$ denotes a set of $d_P$ eigenstates, whose properties are reproduced in the model space, with $d_P$ equal to the dimension of the model space.

The resulting two-body effective interaction $\tilde{V}_{12}$ depends on $A$, on the HO frequency $\Omega$ and on $N_{\text{max}}$, the maximum many-body HO excitation energy (above the lowest configuration) defining the P-space. It follows that $\mathcal{H}^{(1)} + \mathcal{H}^{(2)} - H_{CM}$ is translationally invariant.
and that $\tilde{V}_{12} \to V_{12}$ for $N_{\text{max}} \to \infty$. A significant consequence of preserving translational invariance is the factorization of our wave function into a product of a CM $\frac{2}{3}\hbar \Omega$ component times an internal component. Hence, it is straightforward to correct exactly any observable for the CM effects. This feature distinguishes our approach from most phenomenological shell model studies that involve multiple HO shells.

The most significant approximation used in the present application is the neglect of higher than two-body clusters in the unitary transformed Hamiltonian expansion. Our method is not a variational approach so the neglected clusters can contribute either positively or negatively to the binding energy. Indeed, we find that the character of the convergence depends on the choice of $\Omega$ [6,8,9]. The method can be readily generalized in order to include, e.g., three-body clusters, and to demand the model-space decoupling on the three-body cluster level. Such a generalization leads to the derivation of the three-body effective interaction, which has been successfully applied in our calculations for the $A = 4$ system [8,9]. We learned from these studies that the contribution of higher order clusters to the ground-state energy are about 10% in similar model spaces that we employ here, when an optimal HO frequency is chosen, as it is the case in the present application.

To solve for the properties of $^{12}$C, we employ the m-scheme Many-Fermion Dynamics code [19]. Due to the fast growing matrix dimensions, reaching $6.488 \times 10^4$ at the $N_{\text{max}} = 5$ model space, we are restricted to $N_{\text{max}} = 0, 2, 4$ for the positive-parity states and $N_{\text{max}} = 1, 3, 5$ for the negative-parity states. Here, we utilize $\hbar \Omega = 15$ MeV which lies in the range where the largest model space results are least sensitive to $\hbar \Omega$. Full details will be reported elsewhere.

We present results for the CD-Bonn [20] and the Argonne V8’ [4] NN potentials. Our positive-parity state results are presented in Table I and in Fig. 1, and the negative-parity state results are in Table II and Fig. 2. While the energy of the lowest eigenstate of each parity increases with increasing model space, the relative level spacings are less dependent on model space size. As a gauge of trends with increasing model space size, consider the rms changes in excitation energies of the first 7 excited states of each parity in the CD-Bonn case. For positive parity states, the rms changes are 1.31 (0.22) MeV in going from 0 to 2 (2 to 4)$\hbar \Omega$. For negative parity states, the rms changes are 0.87 (0.20) MeV in going from 1 to 3 (3 to 5)$\hbar \Omega$. The difference between the $N_{\text{max}} = 2(3)$ and 4(5) results is significantly smaller than that between the $N_{\text{max}} = 0(1)$ and 2(3) results which is similar to the convergence trends we saw in lighter systems [3,5,9]. Our obtained binding energy of about 88 MeV in the $4\hbar \Omega$ space is expected to decrease with a further model space enlargement. We estimate, however, that our result should be within 10% of the exact solution for the two-body NN potential used. In order to reach the experimental binding energy, likely a true three-body NN interaction is necessary [1].

In general, we obtain a reasonable agreement of the states dominated by $0\hbar \Omega$ and $1\hbar \Omega$ configurations with experimental levels. We also observe a general trend of improvement with increasing model space size, i.e., the ordering of the $T = 1$ states. We obtain a reasonable set of excitation energies for the $T = 1$ states relative to the lowest $T = 0$ state of each parity. In addition, our lowest $0^+ T = 2$ state lies between 27 and 29 MeV, depending on the NN potential and the model space, in good agreement with the experimental $0^+2$ state at 27.595 MeV. We note that the favorable comparison with available data is a consequence of the underlying NN interaction rather than a phenomenological fit. Our ground-state wave function in the $4\hbar \Omega$ calculation contains about 61% of the $0\hbar \Omega$ component. The occupancy
of the $0p3/2$ level is about 5.74 nucleons, while the occupancy of the $0p1/2$ level is about 1.90 nucleons. From Tables I and II it is clear that the excitation energies of the negative-parity states relative to the positive-parity states decrease rapidly with the model-space enlargement. Still, even in our largest spaces the $3^−0$ state is more than 5 MeV too high compared to the experiment.

In order to achieve a more realistic excitation energy a still larger HO expansion is needed especially for states with significant cluster structure. The two- and higher-$\hbar\Omega$ dominated states, such as the 7.65 MeV $0^+0$ state that is known to be a three-alpha cluster resonance \[23\], are not seen in the low-lying part of our calculated spectra. In general, the convergence rate of the $2\hbar\Omega$ dominated states is quite different than that of the ground state as we observed in $^4$He calculations performed in the present formalism \[8,9\]. Also, an optimal HO frequency for the convergence of the ground state will differ from the optimal frequency for the $2\hbar\Omega$ states. We investigated the position of the lowest $2\hbar\Omega$ dominated states and the giant-quadrupole resonance (GQR) E2 distribution. Our lowest $2\hbar\Omega$ $0^+$ state lies at about 40 MeV excitation energy and the GQR E2 strength is fragmented between 43 to 50 MeV in the $2\hbar\Omega$ calculation. In the $4\hbar\Omega$ model space the excitation energy of the lowest $2\hbar\Omega$ $0^+$ state drops by 5 MeV to about 35 MeV and similarly the GQR strength position is lowered to 37-47 MeV. We note that the experimental GQR strength is observed in the range 18-28 MeV \[24\].

There is little difference between the results from the two NN interactions, although the overall agreement with experiment is slightly better for the CD-Bonn NN potential, in particular for the $T = 1$ states.

Our radius and E2 results, based on the bare radius operator and bare nucleon charges, are smaller than the experimental values. The underestimate of the rms radius, the quadrupole moment and the E2 transitions is linked with the overestimation of the position of the GQR strength and suggests that even in the $N_{\text{max}} = 4$ space we still miss significant clustering effects. We also observe a strong model space dependence of the M1 transitions, $1^+1 → 0^+0$. Clearly, there is still a need for effective operators, which are calculable within our theoretical framework. In general, to compute a two-body correction to a one-body operator in our formalism is more involved than the evaluation of the effective interaction. But, it is easy to study the lowest order renormalization for a two-body operator depending on the relative position of two nucleons as, e.g., the point-nucleon rms radius operator. Then, $O_{\text{eff}} ≈ \sum_{i<j=1}^{A} e^{-S_{ij}} O_{ij} e^{S_{ij}}$. We computed this term for the point-proton rms radius operator and found that the renormalization leads to an increase of the radius and that the size of this increase drops as the model space size increases. The $r_p$ results presented in Table I that were obtained without renormalization should be increased due to the renormalization by about 0.06, 0.02 and 0.01 fm for the $N_{\text{max}} = 0, 2$ and 4 model spaces, respectively. This does not imply that the renormalization of other operators, e.g., the E2 operator, cannot be substantially higher. Similarly, as observed in our $^3$H calculations \[11\], we anticipate that, in contrast with the energies, the higher-order corrections will be more significant and the overall convergence slower for other observables.

We present these results as a useful description of the 0 and $1\hbar\Omega$-dominated states of $^{12}$C. Our wave functions along with the one-body and two-body densities may also be used to predict cross sections for neutrino and muon reactions with $^{12}$C. Such cross sections will be the subject of future investigations. The trends are encouraging and we will carry out
larger model space investigations in order to achieve greater convergence.
