(Dated: July 14, 2014)

Weyl superfluidity or superfluidity, a fascinating topological state of matter, features novel phenomena such as emergent Weyl fermionic excitations and anomalies. Here we report that an anisotropic Weyl superfluid state can arise as a low temperature stable phase in a 3D dipolar Fermi gas. A crucial ingredient of our model is a rotating external field that generates a direction-dependent two-body effective attraction. Experimental signatures are predicted for cold gases in radio-frequency spectroscopy. The finite temperature phase diagram of this system is studied and the transition temperature of the Weyl superfluidity is found to be within the experimental scope for atomic dipolar Fermi gases.

Weyl superfluids or semimetals represent recent developments in generalizing topological phases from gapped to gapless systems (e.g., from topological insulators to semimetals), in condensed matter physics. These Weyl states are characterized by the presence of two (or more) gapless Weyl points, which are topologically protected against small perturbations. The Weyl nodes lead to a variety of fascinating phenomena such as unusual surface states. Hall effects have profound implications for the interesting topological defects. We shall describe this Weyl superfluid state in a 3D magnetic dipolar Fermi gas composed of one hyperfine state, which has been realized in the experimental system of $^{167}$Er recently. The direction of dipole moments can be fixed by applying an external magnetic filed. Let the external field be orientated at a small angle with respect to the xy-plane and rotate fast around the z-axis, the time-averaged interaction between dipoles is effectively attractive. The low temperature phase of this system is predicted as a Weyl superfluid state through the model introduced below.

Effective Model. Consider a 3D spinless dipolar Fermi gas subjected to an external rotating magnetic field

$$B(t) = B \hat{z} \cos \varphi + B \{ \hat{x} \cos \Omega t + \hat{y} \sin \Omega t \},$$

where $\Omega$ is the rotation frequency, $B$ is the magnitude of magnetic field, the rotation axis is $z$, and $\varphi$ is the angle between the magnetic field and the $z$ axis. In strong magnetic fields, dipoles are aligned parallel to $B(t)$. With fast rotations, the effective interaction between dipoles is the time-averaged interaction

$$V(r) = \frac{d^2}{2p^3} (3 \cos^2 \varphi - 1)(1 - 3 \cos^2 \theta) \equiv \frac{d^2}{p^3} (1 - 3 \cos^2 \theta),$$

where $d^2 \equiv d^2 (3 \cos^2 \varphi - 1)$, with the magnetic dipole moment $d$, $r$ is the vector connecting two dipolar particles, and $\theta$ is the angle between $r$ and the $z$ axis. The effective attraction, $V(r) < 0$, is created by making $\cos \varphi < \sqrt{1/3}$, which is our focus in this work.
The effective Hamiltonian of the system above is given by
\[
H = \int d^3r \psi^\dagger(r) \left[ -\frac{\hbar^2 \nabla^2}{2m} - \mu \psi(r) \right] + \frac{1}{2} \int d^3r d^3r' \psi^\dagger(r) \psi^\dagger(r') V(r - r') \psi(r') \psi(r),
\] (2)
where \( \psi(r) \) is the fermion field and \( \mu \) is the chemical potential.

Due to the attractive interaction, fermions tend to pair with each other and form a superfluid state at low temperatures. To study this superfluid state, we construct a general theory to describe a spinless Fermi gas by a fully self-consistent Hartree-Fock-Bogoliubov method. Here, we shall outline the key steps in formulating it in the path integral approach. The details are given in Supplementary Materials. It is known that the thermodynamic properties of the system can be obtained from the partition function which can be expressed in terms of Grassmann fields \( \phi(r, \tau) \) and \( \phi^\dagger(r, \tau) \). By introducing the Hubbard-Stratonovich fields \( \kappa(r, \tau), \lambda(r, r', \tau) \), and \( \Delta(r, r', \tau) \), the quartic fermionic interaction term in the action is decoupled. This makes the partition function Gaussian in the fermionic fields. After integrating over these Grassmann variables, an effective action of the Hubbard-Stratonovich fields is obtained.

Under the saddle-point approximation \( \frac{\delta S_{eff}}{\delta \kappa}|_{\kappa=\langle \kappa \rangle} = 0 \), \( \frac{\delta S_{eff}}{\delta \lambda}|_{\lambda=\langle \lambda \rangle} = 0 \), and \( \frac{\delta S_{eff}}{\delta \Delta}|_{\Delta=\langle \Delta \rangle} = 0 \), we obtain
\[
\langle \kappa(r) \rangle = \int d^3r' V(r - r') \langle \phi^\dagger (r', \tau) \phi(r', \tau) \rangle,
\]
\[
\langle \lambda(r, r') \rangle = -V(r - r') \langle \phi^\dagger (r, \tau) \phi(r, \tau) \rangle,
\]
\[
\langle \Delta(r, r') \rangle = V(r - r') \langle \phi^\dagger (r, \tau) \phi(r, \tau) \rangle.
\] (3)

Here \( \langle \rangle \) stands for the expected average in the ground state of the system. Then, we define the Hartree-Fock self-energy and superconducting gap as
\[
\Sigma(r', r) \equiv \langle \kappa(r) \rangle \delta(r - r') + \langle \lambda(r', r) \rangle,
\]
\[
\Delta(r', r) \equiv \langle \Delta(r', r) \rangle.
\] (4)

3D Uniform dipolar Fermi gas. We now apply the general theory outlined above to the system of 3D uniform spinless dipolar Fermi gas in the presence of a rotating magnetic field. From the symmetry of the system, at least for not too strong interaction strength, we anticipate that pairing only occurs between a particle with momentum \( k \) and another with momentum \(-k\) as in the standard BCS theory. Due to the translational symmetry, it is convenient to study this problem in the momentum space. After Fourier transformation of Eq. (4), the Hartree-Fock self-energy and the pairing gap read
\[
\Sigma_k = V(0)n - \frac{1}{\nu} \sum_{k'} V(k - k') \frac{1}{2} \left[ 1 - \frac{\xi_{k'}}{E_{k'}} \tanh(\frac{\beta}{2} E_{k'}) \right],
\] (5)
\[
\Delta_k = -\frac{1}{\nu} \sum_{k'} V(k - k') \frac{\Delta_{k'}}{2E_{k'}} \tanh(\frac{\beta}{2} E_{k'}),
\] (6)
where \( E_k \) is the quasi-particle excitation energy given by \( E_k = \sqrt{\xi_k^2 + |\Delta_k|^2} \) with the kinetic energy of fermions \( \xi_k = \varepsilon_k + \Sigma_k - \mu \) and \( \varepsilon_k = \frac{\hbar^2 k^2}{2m} \). The interaction between two dipoles in the momentum space is given by \( V(q) = \frac{\Delta_{k'}}{2E_{k'}} (3 \cos^2 \theta_q - 1) \), with the angle \( \theta_q \) between momentum \( q \) and \( z \) axis, \( n \) is the total density, \( v \) is the volume, and \( \beta = 1/(k_B T) \).

It is known that the gap equation (Eq. (6)) has ultraviolet divergence \([27]\). The origin of the divergence can be attributed to the singularity of the dipolar interaction potential for large momentum, or equivalently for short distance. Just as in the treatment of two-component Fermi gas with contact interaction \([28]\), we need to regularize the interaction in the gap equation (Eq. (6)). The divergence can be eliminated by expressing the bare interaction \( V(k - k') \) in Eq. (6) in terms of the vertex function (scattering off-shell amplitude) \([29]\) as
\[
\Gamma(k - k') = V(k - k') - \frac{1}{\nu} \sum_q \Gamma(q - k') \frac{1}{2\pi v} V(q - k'),
\]
and the gap equation will be renormalized as
\[
\Delta(k) = -\frac{1}{\nu} \sum_{k'} \Gamma(k - k') \Delta(k') \left[ \tanh(\frac{\beta E_{k'}}{2}) - \frac{1}{e^{\beta E_{k'}}} \right].
\] (7)

Note that the Hartree term for the selfenergy in Eq. (5), \( V(0)n \) vanishes, since for dipolar interaction in 3D uniform system, \( V(0) = 0 \) \([30]\) and renormalization of the interaction has a negligible effect on the self-energy. Then, the Hartree-Fock self-energy is expressed as
\[
\Sigma_k = -\frac{1}{\nu} \sum_{k'} V(k - k') \frac{1}{2} \left[ 1 - \frac{\xi_{k'}}{E_{k'}} \tanh(\frac{\beta}{2} E_{k'}) \right].
\] (8)

The total density \( n \) can be obtained from the thermodynamic potential \( \Omega = -\frac{1}{\beta} \ln Z \) by using the relation \( N = -\partial \Omega/\partial \mu \),
\[
n = \sum_k \frac{1}{2\nu} \left[ 1 - \frac{\xi_k}{E_k} \tanh(\frac{\beta}{2} E_k) \right].
\] (9)

Under the constraint of Fermi statistics for this single component dipolar Fermi gas, the dominant pairing instability is in the channel with orbital angular momentum \( L = 1 \). The most stable low temperature phase has \( p_x + ip_y \) symmetry, following from the fact that this phase fully gaps the Fermi surface, in contrast to competing phases, such as \( p_x \) or \( p_y \) superfluid state \([31]\). Note that in the presence of a rotating magnetic field, all the dipoles rotating with respect to the \( z \)-axis, so the system has a \( SO(2) \) spatial rotation symmetry. This symmetry is not broken in the \( p_x + ip_y \) pairing state, and we can thus write down the Cooper pair as \( \Delta_k = \Delta(k_x, k_y) e^{ip_k} \), where \( \varphi_k \) is the polar angle of the momentum \( k \) in the x-y plane, to simplify the calculation in Hartree-Fock-Bogoliubov approach.
Weyl Fermions.— With the time-reversal symmetry spontaneously broken in the superfluid state, topological properties emerge in quasi-particle excitations, which are described by a mean field Hamiltonian \[ H_{SF} = \sum_\mathbf{k}\left[\xi_\mathbf{k} c^\dagger_\mathbf{k} c_\mathbf{k} + \Delta_\mathbf{k} c_{-\mathbf{k}} c_\mathbf{k} + \frac{\Delta_\mathbf{k}^2}{2} c^\dagger_\mathbf{k} c^\dagger_{-\mathbf{k}}\right], \]
with \( c_\mathbf{k} \) the fermion annihilation operator. This Hamiltonian can be expressed in the matrix form by
\[
H_{SF} = \sum_\mathbf{k}\left(\left(\begin{array}{cc}
\xi_\mathbf{k} & \frac{\Delta_\mathbf{k}}{2}
\frac{\Delta_\mathbf{k}}{2} & -\xi_\mathbf{k}
\end{array}\right)\right)\left(\begin{array}{c}
c_\mathbf{k}
\frac{\Delta_\mathbf{k}}{\xi_\mathbf{k}} c_{-\mathbf{k}}
\end{array}\right),
\]
where the \( \mathbf{d} \) vector is defined in terms of the Pauli matrices \( \sigma \)'s. The \( d_x, y \) components vanish along the \( z \) axis, whereas along this axis, \( d_z \) vanishes at only two points \( k_x^W \) and \( k_y^W \) (Fig. 2b). In the \( k_x-k_y \) momentum plane with \( k_x^W < k_y < k_y^W \), a skyrmion (see Fig. 1b) is formed from the vector \( \mathbf{d}(\mathbf{k}) \) with a topological charge \( \pm 1 \) (the ‘\( \pm \)' sign reveals the spontaneous time-reversal symmetry breaking), while in other regions \( k_x > k_x^W \) or \( k_z < k_z^W \), the topological charge vanishes. These two gapless points \( k_x^W \) are Weyl nodes, defining the corresponding topological transitions in the momentum space \( S \sim 12 \). Close to the Weyl nodes, the Hamiltonian takes the form of 2 × 2 Hamiltonian of a chiral Weyl fermion [32]. We have checked that the quasi-particle energy dispersion \( E_\mathbf{k} \) is linear, for instance as shown in Fig. 2a when the interaction strength \( J = 3 \) where \( J \equiv \frac{m a^2}{\hbar k_F} \). As shown in Fig. 2a and d, the Weyl nodes are hedgehog-like topological defects of the vector field \( \mathcal{d}(\mathbf{k}) \), which are the point source of Berry flux in momentum space, with a topological invariant \( N_C = \pm 1 \). Here \( N_C \) is defined by \( N_C = \frac{1}{2\pi \hbar^2} \int d\Sigma \cdot \mathcal{G} \frac{\partial \mathcal{G}^{-1}}{\partial \mathcal{k}} - \frac{\partial \mathcal{G}^{-1}}{\partial \mathcal{k}} \mathcal{G} \), where \( \mathcal{G}^{-1} \) is the inverse Green’s function for the quasi-particle excitation, \( \Sigma \) is a 3D surface around the isolated Fermi point \( k_x^W \) or \( k_y^W \), and \( \mathcal{G} \) stands for the trace over the relevant particle-hole degrees of freedom [1]. The quasi-particle excitations near the Fermi points realize the long-sought low-temperature analog of Weyl fermions as originally proposed in particle physics. These Weyl nodes are separated from each other in momentum space. They can not be hybridized, which makes them indestructible, as they can only disappear by mutual annihilation of pairs with opposite topological charges. This is the mechanism of topological stability of this Weyl superfluid state, which is distinct from the spectral-gap protection in insulating topological phases. To characterize the existence of Weyl fermions, we calculate the fermionic density of states (DOS) \[ N(E) = \frac{1}{(2\pi)^3} \int d^3\mathbf{k} \frac{1 + \xi_\mathbf{k}}{2E}(E - E(\mathbf{k})). \]
With linear dispersion near Weyl nodes, we find \[ N(E) \propto E^2. \]
when \( E \to 0 \), which is a direct manifestation of Weyl fermions. This behavior of DOS is confirmed in our numerics (see Fig. 1b). This signature can be measured through the radio frequency spectroscopy technique in atomic Fermi gases [33, 34], which makes the detection experimentally accessible. The other important feature of Weyl fermions realized in this dipolar gas is that they have anisotropic dispersion, reflecting the anisotropy of dipolar interactions. As shown in Fig. 2a, we find that the slope of the quasi-particle dispersion, which stands for the Fermi velocity, is larger when \( \theta = \pi \) than that when \( \theta = \frac{\pi}{2} \), but that when \( \theta = \frac{\pi}{4} \).

Anisotropic superconducting gap. We now discuss the superconducting gap for fermions resulting from anisotropic dipole-dipole interaction. For clarity of demonstration, we take the first-order Born approximation by replacing the vertex function \( \Gamma(\mathbf{k} - \mathbf{k}') \) in the gap equation (Eq. (7)) by the bare dipolar interaction \( V(\mathbf{k} - \mathbf{k}') \). By numerically solving the Hartree-Fock self-energy equation (Eq. (8)), the gap equation (Eq. (7)), and number equation (Eq. (9)) self-consistently, the superconducting gap anisotropy has been investigated. As shown in Fig. 3d, the magnitude of the order parameter (superconducting gap) on the Fermi surface \( \Delta_0 \) monotonically increases with \( |\theta| \), whereas along the \( z \) axis, where the unit of momentum is the Fermi momentum \( k_F \). (b) Quasi-particle excitation dispersion around the gapless points. The slope of the quasi-particle dispersion is larger when \( \theta = \frac{\pi}{2} \) than that when \( \theta = \frac{\pi}{4} \). (c) and (d) Hedgehog-like topological defects of two Weyl nodes. (a) A skyrmion formed from the vector \( \mathbf{d} \) defined in the main text. (b) Density of states (DOS) which has been defined in the main text in units of \( n_F / E_F \) where \( n_F = \frac{k_F^3}{6\pi m} \) and \( E_F = \frac{k_F^2}{2m} \).
direction perpendicular to the dipoles, say \( k \) and \( z \) axis. The maximum value of \( \Delta_0 \) is reached in the direction perpendicular to the dipoles, say \( \theta = \frac{\pi}{2} \). In the direction of the dipoles, namely \( \theta = 0 \) the order parameter vanishes. Fig. 3b also shows that the order parameter is dependent on the modulus of the momentum of superconducting gap. This can be understood from the analysis of the gap equation (Eq. (7)) that the main contribution to the integral comes from the region of small momentum which is close to the Fermi momentum. The anisotropy of the order parameter provides a crucial difference from both \( s \) [28] and \( p \)-wave pairing [35] due to a short-range attractive interaction. This anisotropy ensures the anisotropic momentum dependence of the gap in the spectrum of single particle excitations. For example, excitations with momenta perpendicular to the direction of the dipoles acquire the largest gap. In contrast to this, the excitations with momenta in the direction of the dipoles remain unchanged. Therefore, the response of this dipolar superfluid Fermi gas to small external perturbations will have a pronounced anisotropic character.

Finite temperature phase transition. Upon increasing temperature the Weyl superfluid state will undergo a phase transition to a normal state. By numerically solving the Hartree-Fock self-energy equation (Eq. (5)), gap equation (Eq. (7)), and number equation (Eq. (9)) self-consistently at finite temperature, the BCS transition temperature is obtained as shown in Fig. 5. We find that the BCS transition temperature is a monotonically increasing function of the interaction strength \( J \). However, the strong enough interaction will cause the system to suffer from the mechanical instability. The reason for that is as follows. The magnitude of superconducting gap increases with enhancing the interaction strength. Due to the attractive nature of the effective interaction between dipoles, the free energy of this dipolar gas is smaller than that of an ideal Fermi gas. This energy reduction increases with the interaction strength (or equivalently the density of the gas with a certain dipole moment). When the interaction strength is large enough, the effect of the interaction is dominant and the system can be unstable. As shown in Fig. 4 the chemical potential is a monotonically decreasing function when the density is above a critical value, and the compressibility is negative, indicating that the superfluid state is dynamically unstable. By considering the mechanical instability of the system, as shown in Fig. 5 the finite temperature phase diagram is obtained. We find that the BCS transition temperature of a stable superfluid state can reach around \( 0.2E_F \) at mean-field level, which approaches to the current experimental temperature region [14, 16].

In the current experiments, for example, \(^{167}\text{Er}\) atom’s magnetic dipole moment is \( 7\mu_B \) and the density of the system is about \( n = 4 \times 10^{14} \text{cm}^{-3} \). The Fermi energy is given by \( E_F = \frac{\hbar^2}{2m} (6\pi^2 n)^{2/3} \approx 0.16 \text{MHz} \) and the corresponding Fermi temperature is \( T_F = \frac{E_F}{k_B} \approx 1 \mu\text{K} \). To increase the effective attraction, one may consider adding a shallow optical lattice. For instance with lattice strength \( V = 6E_R \), the BCS transition temperature can reach around \( 3\text{nK} \). A similar estimate can be obtained for \(^{161}\text{Dy}\) atom which has a larger magnetic dipole moment of \( 10\mu_B \), the corresponding dipolar interaction strength is around two times larger than that of \(^{167}\text{Er}\). Under the same condition, the BCS transition temperature can reach around \( 50\text{nK} \). This high transition temperature \( T_c \) makes it realistic to obtain the Weyl superfluid state in ex-
paths.

Conclusion. We propose that an anisotropic Weyl superfluid state can be realized in a 3D spinless dipolar Fermi gas. The crucial ingredient of our model is the presence of a rotating magnetic field, which gives rise to the direction-dependent effective attraction between dipoles supporting the pairing state. The long-sought low-temperature analog of Weyl fermions of particle physics has been found in the quasiparticle excitations in this superfluid state. The stability and the transition temperature are also studied, which will be useful for exploring this Weyl superfluid state in future experiments.

Supplementary Materials

PATH INTEGRAL APPROACH

From the Hamiltonian in Eq. (2), by introducing Grassmann fields \( \phi(\mathbf{r}, \tau) \) and \( \phi^*(\mathbf{r}, \tau) \), we express grand partition function of the system as (the units are chosen as \( \hbar = k_B = 1 \))

\[
Z = \int D\phi D\phi^* e^{-S}, \quad (S1)
\]

with the action

\[
S[\phi, \phi^*] = S_0[\phi, \phi^*] + S_{int}[\phi, \phi^*],
\]

and

\[
S_0[\phi, \phi^*] = \int d\tau \int d^3 \mathbf{r} \int d^3 \mathbf{r}' \phi^*(\mathbf{r}, \tau) \left[ \frac{\partial}{\partial \tau} - \frac{\nabla^2}{2m} - \mu \right] \delta(\mathbf{r} - \mathbf{r}') \phi(\mathbf{r}', \tau),
\]

\[
S_{int}[\phi, \phi^*] = \frac{1}{2} \int d\tau \int d^3 \mathbf{r} \int d^3 \mathbf{r}' \phi^*(\mathbf{r}, \tau) \phi^*(\mathbf{r}', \tau) V(\mathbf{r} - \mathbf{r}') \phi(\mathbf{r}', \tau) \phi(\mathbf{r}, \tau).
\]

The quartic fermionic interaction term in the action in Eq. (S1) can be decoupled by introducing Hubbard-Stratonovich fields \( \kappa(\mathbf{r}, \tau), \lambda(\mathbf{r}, \mathbf{r}', \tau), \) and \( \Delta(\mathbf{r}, \mathbf{r}', \tau) \). This leads to a partition function with the action

\[
S[\phi, \phi^*, \kappa, \lambda, \lambda^*, \Delta^*] = - \int d\tau \int d^3 \mathbf{r} \int d^3 \mathbf{r}' \left\{ \frac{1}{2} \left[ \kappa(\mathbf{r}, \tau) \right. \right.
\]

\[
V^{-1}(\mathbf{r} - \mathbf{r}') \kappa(\mathbf{r}', \tau) + \frac{[\lambda(\mathbf{r}, \mathbf{r}', \tau)]^2}{V(\mathbf{r} - \mathbf{r}')} + \frac{[\Delta(\mathbf{r}, \mathbf{r}', \tau)]^2}{V(\mathbf{r} - \mathbf{r}')}
\]

\[
- \int d\tau \int d^3 \mathbf{r} \int d^3 \mathbf{r}' [\phi^*(\mathbf{r}, \tau), \phi(\mathbf{r}, \tau)] \mathbf{G}^{-1}(\mathbf{r}, \mathbf{r}', \tau)
\]

\[
\phi^*(\mathbf{r}', \tau) \bigg],
\]

where

\[
\mathbf{G}^{-1}(\mathbf{r}, \mathbf{r}', \tau) = \frac{1}{2} (\mathbf{G}_0^{-1}(\mathbf{r}, \mathbf{r}', \tau) - \left[ \begin{array}{cc} 0 & \tilde{\Delta}(\mathbf{r}, \mathbf{r}', \tau) \\ -\tilde{\Delta}^*(\mathbf{r}, \mathbf{r}', \tau) & 0 \end{array} \right]),
\]

with

\[
\mathbf{G}_0^{-1}(\mathbf{r}, \mathbf{r}', \tau) = \left[ \begin{array}{cc} G_0^{-1}(\mathbf{r}, \mathbf{r}', \tau) & 0 \\ 0 & -G_0^{-1}(\mathbf{r}', \mathbf{r}, \tau) \end{array} \right],
\]

and

\[
G_0^{-1}(\mathbf{r}, \mathbf{r}', \tau) = -\left[ \left( \frac{\partial}{\partial \tau} - \frac{\nabla^2}{2m} - \mu + \kappa(\mathbf{r}, \tau) \right) \delta(\mathbf{r} - \mathbf{r}') + \lambda(\mathbf{r}', \mathbf{r}, \tau) \right].
\]
After integrating out the fermion fields, the effective action is obtained

\[ S_{\text{eff}}[\kappa, \lambda, \lambda^*, \tilde{\Delta}, \tilde{\Delta}^*] = - \int d\tau \int d^3r \int d^3r' \frac{1}{2} \nabla^2 \kappa(r, \tau) \]

\[ V^{-1}(r - r') \kappa(r', \tau) + \frac{|\lambda(r, r', \tau)|^2}{V(r - r')} + \frac{|\tilde{\Delta}(r, r', \tau)|^2}{V(r - r')} \]

\[ - \text{Tr} \ln(-G^{-1}) \]

Using the saddle point condition, the Hartree-Fock self-energy and superconducting gap are obtained as shown in Eq. (4).
