Research

Keywords: 16S rRNA, airway microbiota, infection, lung transplant, rejection
Abstract

Background

Infection and rejection are the two most common complications after lung transplantation (LT) and are associated with increased morbidity and mortality. The differential diagnosis of infection and rejection is sometimes difficult due to similar clinical manifestations. However, few studies have investigated the airway microbiota between lung transplant recipients (LTRs) with infection and rejection.

Results

A total of 181 sputum samples (event-free, n=47; infection, n=103; rejection, n=31) were collected from 59 LTRs. A distinct airway microbiota was observed among clinically stable (or event-free) recipients and those with infection or acute rejection after LT. Alpha and beta diversity were significantly different between event-free and rejection recipients and between infection and rejection recipients. Ten differential genera were identified by linear discriminant analysis effect size (LEfSe), with *Corynebacterium*, unclassified *Enterococcaceae* and unclassified *Lactobacillales* enriched in recipients with infection, and *Rothia*, *Granulicatella*, *Neisseria*, *Actinomyces*, *Leptotrichia*, *Lactobacillus* and unclassified *Aerococcaceae* more abundant in LTRs with acute rejection. Random forest analyses indicated that the combination of the 10 microbiota constituents and procalcitonin (PCT) and T-lymphocyte levels showed AUCs of 0.894, 0.955 and 0.913 to differentiate between event-free and infection, event-free and rejection, and infection and rejection recipients, respectively.

Conclusions

Our study is the first to compare the airway microbiota between LTRs with infection and acute rejection. The airway microbiota, especially combined with PCT and T-lymphocyte levels, showed satisfactory predictive efficiency in discriminating among clinically stable recipients and those with infection and acute rejection, suggesting that the airway microbiota was an indicator to differentiate between infection and acute rejection after LT.

Background

Lung transplantation (LT) is the only therapeutic option for patients with end-stage lung disease and short-term graft survival has improved over decades. However, the survival of lung transplant recipients (LTRs) is limited compared with that of other solid organ transplant recipients [1]. The low survival rate is predominantly due to infection- and rejection-related complications, which are the two major threats for LTRs in both early and long-term follow-up [1,2]. Severe acute rejection often occurs after LT, and various infections due to an immunosuppressed state and the unique anatomy and physiology of the transplanted lung also occur frequently [2]. As a result, rejection and infection affect and interact with each other, and balancing rejection and infection is the major challenge of LT [3]. Many studies have revealed the importance of the airway microbiota in local and systemic immunity, and airway microbiota
dynamics play a very important role in the development and pathophysiology of respiratory diseases [4-6]. This suggests that the airway microbiota may affect the immune response and therefore the balance between infection and rejection in LTRs.

Over the past decades, several studies have observed an altered airway microbiota in LTRs compared with that in healthy controls and pretransplant patients [7-9]. For example, Charlson et al. found that LTRs have lower microbial richness and diversity but a higher bacterial burden in bronchoalveolar lavage fluid (BALF) than control subjects [7]. Syed and colleagues demonstrated a similar alpha diversity and a distinct beta diversity of the airway microbiota between pre- and post-LT [8]. In addition, Pseudomonadaceae, Enterobacteriaceae and Staphylococcaceae were enriched in LTRs, while Prevotellaceae, Veillonellaceae and Streptococcaceae were frequently detected in nontransplant individuals [9]. Importantly, increasing evidence has indicated a close relationship between the airway microbiota and the disease progression and outcome of LTRs [10-12]. In summary, investigation of the airway microbiota may improve our understanding of the mechanisms involved in allograft dysfunction and may suggest potential therapies to improve survival for LTRs.

In addition to the immunosuppressed state, LTRs are more susceptible to infection because of direct exposure to the external environment, a defective cough reflex and damaged mucociliary clearance compared with those in other organ transplant patients [2,13]. Respiratory infection is the main cause of death within the first year after LT, with bacteria being the most frequent cause [13,14]. A recent study suggested a distinct airway microbiota in LTRs between respiratory infection and colonization without respiratory infection [15], and loss of airway microbial diversity can increase the risk of infection [9]. BALF neutrophilia was found to be associated with lower microbial diversity, indicating a correlation between the airway microbiota and infection after LT [16]. Allograft rejection is another common complication after LT and is associated with increased morbidity and mortality [3]. Previous studies have revealed a significant relationship between the airway microbiota and acute rejection. For example, low microbial diversity was associated with acute rejection [17], while microbiome phenotypes dominated by Actinobacteria reduced the risk of developing acute rejection [12]. Overall, these studies indicated a close relationship between the airway microbiota and infection and rejection of LTRs.

Although clinicians try to monitor these two complications carefully, the diagnostic options are limited. The diagnosis of infection requires clinicians to identify the source and carry out pathogen specific tests. The pathological assessment of transbronchial biopsies, which is the gold standard for the diagnosis of acute rejection after LT, is an invasive procedure with limited predictive value [18]. However, both of post-transplant infection and acute rejection may be accompanied by signs of similar clinical features, including cough, shortness of breath and radiological infiltrate, thus resulting in difficult differential diagnosis [19]. Considering the high morbidity and mortality of infection and rejection in LTRs and the bidirectional relationship between them, clinical decision-making depends on accurate diagnosis of both infection and rejection. Recent studies have revealed an association between the airway microbiota and infection or rejection after LT. However, few studies have investigated the specific microbial differences between infection and acute rejection recipients. Whether there are potential indicators to distinguish
between infection and acute rejection in LTRs remains unknown. In this cross-sectional study, we analyzed the airway microbial profiles associated with infection and acute rejection in LTRs.

**Methods**

**Study population**

A total of 181 sputum samples collected from 59 adult LTRs were enrolled in our study at the First Affiliated Hospital of Guangzhou Medical University (Guangzhou, China) between June 2017 and December 2019. Clinical information collected from the recipients included standardized medical record abstraction, including the demographic data, transplant data, laboratory examination and clinical diagnosis of the recipients (Table 1).

Adult LTRs (age >18 years) hospitalized in the First Affiliated Hospital of Guangzhou Medical University from June 2017 to December 2019 were included. The exclusion criteria included intubation or mechanical ventilation or other complications (e.g., bleeding, anastomotic complications, pneumothorax, etc.) at the time of sampling. The diagnostic criteria for respiratory infection were based on clinical (such as fever, cough, sputum production and radiographic infiltrate) and microbiological grounds [14,20]. Acute rejection was diagnosed by transbronchial lung biopsy according to the International Society for Heart and Lung Transplantation (ISHLT) criteria [21]. Clinically stable recipients (or event-free) were defined as having neither infection nor rejection. Each sample was assigned a diagnosis of infection, acute rejection or event-free independently by two experienced clinicians. In the case of disagreement, a third clinician was consulted (for more details, please see the Supplementary Material).

**Data collection**

For each enrolled subject, we collected demographic data, operation-related data, laboratory tests and pharmacological treatment. Except for operation-related data collected during or after LT, other data were collected at the time of sampling. Laboratory data, including cell counts/percentages in the blood and BALF, the biomarkers of inflammation (PCT) and microbiological data, were provided by the clinical laboratory of the First Affiliated Hospital of Guangzhou Medical University. The absolute count of total T lymphocytes (CD3⁺) in peripheral blood was determined by flow cytometry using the Cytomics FC500 cytometer. Serum PCT was measured using an electrochemical luminescence immunoassay. PGD was diagnosed and graded based on pulmonary edema on chest X-ray and the PaO₂/FiO₂ ratio according to the 2016 ISHLT consensus statement [22].

**Sample collection, DNA extraction and 16S rRNA gene sequencing**

Sputum samples were obtained by induced sputum of hypertonic or isotonic saline with salbutamol according to the Task Force on Induced Sputum of the European Respiratory Society [23]. All samples were immediately stored at -80°C for subsequent DNA extraction. The V3-V4 hypervariable region of the 16S rRNA gene was amplified by PCR, and the amplicons were sequenced using the Illumina NovaSeq
6000 platform (Guangzhou, China). Full details about the DNA amplification, purification and preparation for sequencing are provided in our previous study and in the Supplementary Material [24,25].

Subsequent sequence processing and analysis were performed using the Quantitative Insights into Microbial Ecology 2 (QIIME2) platform [26]. The barcode primers were removed if they contained ambiguous reads or mismatches in the primer sequences following the barcoded Illumina paired-end sequencing (BIPES) protocol [27]. We screened and removed chimeras using UCHIME in de novo mode to obtain high-quality sequence reads [28]. Representative sequences were aligned using Python Nearest Alignment Space Termination (PyNAST) against the Greengenes database [29]. The bioinformatics procedure is documented in https://github.com/lichunxi0/Lung-transplant/tree/main. Sequences were clustered into operational taxonomic units (OTUs) with 97% sequence similarity using USEARCH [30]. The 16S rRNA gene sequences were classified into specific taxa using the Ribosomal Database Project (RDP) classifier [31]. Additional details are provided in the Supplementary Material.

**Statistical analysis**

The Shannon index was used to evaluate the alpha diversity (within-sample diversity). Principal coordinate analysis (PCoA) based on the unweighted UniFrac distance matrix was performed to calculate beta diversity (dissimilarity between samples). Differential taxa between groups were identified using the linear discriminant analysis (LDA) effect size (LEfSe) method with a threshold set at 2.0 for the LDA score [32]. Redundancy analysis (RDA) was performed to evaluate the relationship between clinical characteristics and different groups. Random forest models were used to classify the LTRs with different diagnoses and evaluate the importance of indicator using the R “randomForest” package [33]. The performance of the model was evaluated using a 10-fold cross-validation approach and measured using a receiver operating characteristic (ROC) curve (“pROC” package). The area under the ROC curve (AUC) was determined to assess the ROC effect. Clinical characteristics were evaluated using SPSS (v20.0) software, and Figures were generated using GraphPad Prism (v7.0), Canoco (v5.0), TBtools (v1.051) and R (v2.1.1) software.

**Results**

After sequencing, a total of 181 sputum samples from 59 LTRs were included for subsequent analysis (Fig. 1). We divided the recipients into three groups according to the presence or absence of pulmonary infection and acute rejection at sampling: clinically stable (or event-free, n=47) recipients, recipients with infection (n=103) and recipients with rejection (n=31). The clinical characteristics of the LTRs are presented in Table 1.

Clinical characteristics, such as laboratory parameters, hospital stay, intensive care unit (ICU) stay, primary graft dysfunction (PGD) grade and pulmonary function, are regarded as factors that influence both clinical diagnosis and the airway microbiota. To assess the contribution of clinical variables to microbial community composition and clinical diagnosis, RDA was performed at the OTU level. The results showed that the event-free, infection and rejection groups could be distinguished from each other,
and several clinical characteristics, such as hospital stay, ICU stay and serum PCT, were highly positively associated with the airway microbiota of infection recipients, while T lymphocytes were positively related to rejection recipients (Fig. S1).

The airway microbial community in LTRs with different transplant outcomes

First, we compared the airway microbial diversity among LTRs with different clinical diagnoses. Alpha diversity was significantly different between the event-free and rejection and between the infection and rejection groups (\(P<0.011, P=0.001\), respectively), with the highest Shannon index in the rejection group (Fig. 2A). PCoA based on the unweighted UniFrac distance matrix showed a distinct beta diversity among the 3 transplant groups (\(P=0.001, R^2=0.13\), Fig. 2B), as well as between the event-free and rejection groups and between the infection and rejection groups (\(P=0.004, R^2=0.03; P=0.001, R^2=0.02\); respectively, Fig. 2D, E). However, the event-free and rejection groups were not clearly separated in alpha (Shannon, \(P=0.136\)) and beta diversity (unweighted UniFrac, \(P=0.35, R^2=0.01\), Fig. 2C).

Additionally, a heat map of the 28 dominant genera (relative abundance >1% in at least one group) showed a different microbial profile among the 3 groups (Fig. 3A). A Venn plot was drawn at the family, genus and OTU levels with relative abundance >1% among the different groups (Fig. 3B, C, D). The results showed that 13 families, 13 genera and 8 OTUs were shared by the event-free, infection and rejection recipients. Several microbial taxa were unique to the 3 groups, including 1 family, 2 genera and 6 OTUs in the event-free group; 2 families, 3 genera and 8 OTUs in the infection group; and 1 family, 1 genus and 5 OTUs in the rejection group. This finding indicated that the 3 groups not only shared a common microbiota but also had their own unique taxa which may associated with the pathogenesis of both diseases.

Changes in the airway microbiota during infection and rejection of LTRs

The top 6 most abundant phyla of the airway microbiota detected in our study were Firmicutes, Proteobacteria, Actinobacteria, Bacteroidetes, Cyanobacteria and Fusobacteria. The 28 dominant genera with an average relative abundance greater than 1% in at least one group (mainly \(Streptococcus\), \(Rothia\), \(Enterococcus\), \(Haemophilus\) and \(Granulicatella\)) accounted for up to 90% of the total genera. The microbial composition of the airway microbiota at the phylum level and the genus level was distinct among the event-free, infection and rejection recipients (Fig. 4A, B).

Moreover, LEfSe on all bacterial taxa was used to identify the different microbiota constituents among the 3 transplant groups (LDA score >2.0, Fig. S2). To more clearly explore microbial differences among the 3 groups, we selected the above 28 dominant genera to build the LEfSe plot, and a total of 10 distinguished genera were identified (Fig. 4C). Three genera, namely, \(Corynebacterium\), unclassified \(Enterococccaceae\) and unclassified \(Lactobacillales\) were greatly enriched in the infection group, and 7 genera, namely, \(Rothia\), \(Granulicatella\), \(Neisseria\), \(Actinomyces\), \(Leptotrichia\), \(Lactobacillus\) and unclassified \(Aerococccaceae\), were significantly enriched in the rejection group, while no differentially
abundant genera were found in clinically stable recipients. Table S1 compares the relative abundance and prevalence of the 10 genera in the 3 groups.

The prediction efficiency of the airway microbiota and clinical features for different clinical diagnoses of LTRs

Finally, we attempted to evaluate whether there were useful adjunctive indicators for the discrimination of different transplant groups. Generally, increases in serum PCT and peripheral blood T-lymphocyte levels are associated with infection and acute rejection after LT, respectively [34,35]. In our study, PCT and T-lymphocyte levels were relatively high in the recipients with infection and rejection, respectively, but the differences were not statistically significant (Fig. 5A, B). Therefore, random forest analysis was performed using individual airway microbiota constituents alone or in combination with clinical variables (PCT and T-lymphocyte levels) to investigate their prediction efficiencies in LTRs with different clinical diagnoses. First, the ROC curve was determined using the above 10 potential indicators identified by LEfSe, with AUC values of 0.697 (95% CI: 68.45-71.03%), 0.854 (95% CI: 84.13-86.63%) and 0.822 (95% CI: 81.08-83.28%) to distinguish between the event-free and infection, event-free and rejection, and infection and rejection groups, respectively (Fig. 5C). In comparison, the model was built based on the combination of the 10 genera and PCT and T lymphocyte levels. The results revealed an improved performance, and the corresponding AUCs reached 0.894 (95% CI: 88.54-90.34%), 0.955 (95% CI: 94.78-96.24%) and 0.913 (95% CI: 90.28-92.31%, Fig. 5D). These results indicated that the airway microbiota, especially combined with PCT and T lymphocyte levels, was a reliable indicator of infection and acute rejection in LTRs.

Discussion

In this study, we explored the relationship between airway microbiota and infection and acute rejection of LTRs. A significantly different airway microbiota was observed among event-free, infection and rejection recipients. The ten most differential genera identified by LEfSe were considered to be potential indicators for infection and acute rejection diagnosis in LTRs, including *Corynebacterium*, unclassified *Enterococccaceae*, unclassified *Lactobacillales*, *Rothia*, *Granulicatella*, *Neisseria*, *Actinomyces*, *Leptotrichia*, *Lactobacillus* and unclassified *Aerococccaceae*. Furthermore, a combination of the 10 genera and PCT and T lymphocyte levels indicated great discrimination for different clinical diagnosis, suggesting that the airway microbiota may be a useful indicator for infection and acute rejection diagnosis in LTRs.

Previous studies have found lower microbial richness and diversity but a higher bacterial burden in the lungs of LTRs than in those of control subjects [7], as well as a similar alpha diversity and a distinct beta diversity in the airways before and after LT [8]. However, few studies have reported microbial differences among clinically stable, infection and rejection LTRs. In this study, we found different alpha and beta diversities between event-free and rejection groups and between infection and rejection groups, but no marked difference in either alpha or beta diversity was found between event-free and infection recipients. Venn plots indicated both similarities and differences among the 3 transplant groups. Microbiota
composition analysis revealed microbial changes following different diagnoses of LTRs. Moreover, LEfSe identified 3 and 7 genera that were specifically enriched in infection and rejection recipients respectively. *Corynebacterium*, unclassified *Enterococcaceae* and unclassified *Lactobacillales* were enriched in infection recipients, while *Rothia, Granulicatella, Neisseria, Actinomyces, Leptotrichia, Lactobacillus* and unclassified *Aerococcaceae* were more abundant in rejection LTRs. Taken together, these results suggest a close association between the airway microbiota and infection and acute rejection in LTRs.

Among the 10 most differential genera, *Corynebacterium* is considered a proinflammatory bacterium associated with catabolic remodeling in the transplanted lung [36]. *Enterococcus*, the major genus of the family Enterococcaceae, is one of the most frequent pathogens during the first year after LT [37]. Our results showed significantly elevated abundances of *Corynebacterium* and unclassified *Enterococcaceae* in recipients with infection, which may therefore support their more important roles in transplant infection. In addition, *Rothia, Granulicatella, Neisseria, Actinomyces, Leptotrichia, Lactobacillus* and unclassified *Aerococcaceae* have been found to be associated with asthma [38-44], suggesting an interaction between these microbiota constituents and the immune system in the lung. In the current study, these 7 bacterial genera were enriched in recipients with acute rejection, indicating that these genera may be involved in the immune response in acute rejection. However, few studies have reported the role of these 7 bacterial genera in allograft lung rejection, and the mechanism remains unknown.

Infection and rejection are very common complications associated with increased morbidity and mortality following LT [13]. Unfortunately, the differential diagnosis of infection and rejection is sometimes difficult due to similar clinical manifestations [19,45]. Several studies have suggested that upregulated PCT levels reflect the presence of infective complications after solid organ transplantation and LT [34,45]. T-lymphocyte is regarded as the major immune lymphocytes responsible for lung allograft rejection [35,46,47]. An increase in peripheral blood T-lymphocyte counts was observed during acute lung rejection [48]. However, in our results, infection and rejection recipients showed only a slight increase in PCT and T lymphocyte levels compared with those in the other 2 groups (P>0.05). Therefore, we attempted to seek another indicator to differentiate infection from rejection. We performed random forest analyses and achieved a satisfactory prediction effect of the airway microbiota, especially with the above 10 differential genera identified by LEfSe (*Corynebacterium*, unclassified *Enterococcaceae* and unclassified *Lactobacillales, Rothia, Granulicatella, Neisseria, Actinomyces, Leptotrichia, Lactobacillus* and unclassified *Aerococcaceae*), for distinguishing between different clinical diagnoses (event-free vs. infection, AUC=0.697; event-free vs. rejection, AUC=0.854; infection and rejection, AUC=0.822). Furthermore, a better classification efficacy of the combination of the 10 microbiota constituents and PCT and T lymphocyte levels was assessed: event-free vs. infection, AUC=0.894; event-free vs. rejection AUC=0.955; and infection and rejection, AUC=0.913. Overall, these findings further confirmed the importance of the 10 airway microbiota constituents in transplant infection and rejection, and provided important evidence that the airway microbiota was potentially helpful in predicting infection and acute rejection in LTRs. Nevertheless, biomarker-based models still need to be confirmed with larger samples.
Notably, our study is the first to compare the airway microbial profiles between recipients with infection and rejection after LT, as well as to evaluate the use of airway microbiota in differentiating between LTRs with infection and rejection. Another strength of this study is a relatively large number of LTRs and the first exploration of the airway microbiota in Chinese LTRs using high-throughput technology [12,49]. A major limitation is the cross-sectional design that provides only the possible relationships between the airway microbiota and infection and rejection in LTRs. Larger studies are needed to repeat and confirm these findings, and future in vivo and in vitro experiments are needed to determine the microbial-mediated mechanism. Moreover, the dynamic changes in the airway microbiota may be more reliable and meaningful.

**Conclusion**

In summary, we conducted one of the first studies to explore the relationship between the airway microbiota and infection and acute rejection of LTRs. *Corynebacterium*, unclassified *Enterococcaceae*, and unclassified *Lactobacillales* were enriched in patients with infection, while *Rothia*, *Granulicatella*, *Neisseria*, *Actinomyces*, *Leptotrichia*, *Lactobacillus* and unclassified *Aerococcaceae* were enriched in recipients with acute rejection. The combination of airway microbiota with PCT and T-lymphocyte levels may complement the deficiencies of the diagnosis of acute rejection and infection in LTRs and thus improve the treatment and clinical outcomes of patients after LT. In the future, it seems important to understand the detailed role of the airway microbiota in the mechanism and development of infection and acute rejection after LT.

| *Aspergillus* sp.       | 15 (8.3%)  | 0 (0.0%)    | 15 (14.6%) | 0 (0.0%)  |
|                             | No. (%)          |
|-----------------------------|------------------|
| **Candida sp.**             | 5 (2.8%)         |
| **Blood CMV DNA**           | 11 (6.1%)        |
| **Antibiotics**             |                  |
| Meropenem/Vancomycin        | 90 (49.7%)       |
| Piperacillin/Cefoperazone   | 72 (39.8%)       |
| TMP/SMX                     | 29 (16.0%)       |
| Azithromycin                | 4 (2.2%)         |
| **Immunosuppression**       |                  |
| Glucocorticoid              | 181 (100%)       |
| Tacrolimus                  | 163 (90.1%)      |
| Mycophenolate mofetil       | 158 (87.3%)      |

Data are the mean±SD or n (%) as appropriate. BMI, body mass index; COPD, chronic obstructive pulmonary disease; ILD, interstitial lung disease; PGD, primary graft dysfunction; CMV, cytomegalovirus; TMP/SMX, trimethoprim/sulfamethoxazole.

#At sampling.

§Positive bacterial culture could be to the presence of respiratory pathogens or colonized bacteria. If there was no clear clinical evidence for respiratory infection or no previous culture for reference, the microorganisms in sputum were defined as colonized bacteria.
