Abstract

By adapting Feynman’s sum over paths method to a quantum mechanical
system whose phase space is a torus, a new proof of the Landsberg-Schaar iden-
tity for quadratic Gauss sums is given. In contrast to existing non-elementary
proofs, which use infinite sums and a limiting process or contour integration,
only finite sums are involved. The toroidal nature of the classical phase space
leads to discrete position and momentum, and hence discrete time. The corre-
sponding ‘path integrals’ are finite sums whose normalisations are derived and
which are shown to intertwine cyclicity and discreteness to give a finite version
of Kelvin’s method of images.

1 Introduction

In this paper we give a new proof, using only finite sums and avoiding the need for
analytic methods, of the Landsberg-Schaar formula for quadratic Gauss sums. The
key idea, which springs from earlier work of one of us [1], is to apply the quantization

1Science Laboratories, South Road, Durham DH1 3LE, J.V.Armitage@durham.ac.uk
2Strand, London WC2R 2LS, alice.rogers@kcl.ac.uk
of a quantum mechanical system whose phase space is a torus, with both position
and momentum (and also time) discrete and cyclic. On adapting Feynman’s ‘sum
over paths’ method to this system a discrete and finite version of Kelvin’s method of
images is obtained.

The formula states that for positive integers \( p \) and \( q \)

\[
\frac{1}{\sqrt{p}} \sum_{n=0}^{p-1} \exp\left(\frac{2\pi in^2q}{p}\right) = \frac{e^{\pi i/4}}{\sqrt{(2q)}} \sum_{n=0}^{2q-1} \exp\left(-\frac{\pi in^2p}{2q}\right). 
\]

(1)

In number theory this formula plays a central rôle, underpinning key results relating
to quadratic reciprocity and characters. The formula also promises to be a useful
adjunct to discrete Fourier transform methods used, for instance, in some algorithms
for quantum computing [2]. In this context it essentially provides the discrete inverse
quantum Legendre transformation from the free Hamiltonian to the free Lagrangian.

The standard proof of the Landsberg-Schaar formula (as given, for example, in
[3]) is obtained by putting \( \tau = \frac{2iq}{p} + \epsilon, \epsilon > 0 \), in the Jacobi identity for the theta
function:

\[
\sum_{n=-\infty}^{+\infty} e^{-\pi n^2 \tau} = \frac{1}{\sqrt{\tau}} \sum_{n=-\infty}^{+\infty} e^{-\pi n^2 / \tau},
\]

and then letting \( \epsilon \to 0 \). This method is an example of Hecke’s observation that
‘exact knowledge of the behaviour of an analytic function in the neighbourhood of its
singular points is a source of arithmetic theorems’ [4] p225.

While this method certainly establishes the truth of the formula, Hecke’s insight
notwithstanding it is somewhat unsatisfactory to have to use analytic methods and
take limits when only finite sums are involved. The proof given in this paper does
remain entirely in the arena of finite sums; it demonstrates the extraordinary range of
Feynman’s method of ‘summing over histories’, which here extends to the discrete and
cyclic regime in a pleasing and effective way. So, in a sense, the quantum mechanics
offers another example of Hecke’s insight

The key ingredient in this paper is quantization on a toroidal phase space. A
first step was taken by one of us in [1], leading to a proof of the Jacobi identity
by using random walks to quantize a system with cylindrical phase space. The key
idea here is the observation that the series \( \vartheta(it) = \sum_{n=-\infty}^{+\infty} e^{-\pi n^2 it} \) is the trace of a
certain quantum evolution operator \( \exp(-iHt/\hbar) \), which converges in the distribution
sense. Using path integral methods adapted to the cylinder, in particular Kelvin’s
method of images [3], an alternative formula for the trace is found, and equating the
two expressions gives the Jacobi identity. This work is described in section 2 as an
introduction to the main result in this paper.
With a minor change of emphasis, the formula (1) turns up by taking the operator that gives (2) (for $\tau = it$) and then ‘looking at the system at discrete times $\tau = -2i/p$’. This idea is pursued in section 3. In order to remove difficulties over convergence, and to obtain the Landsberg-Schaar formula (1), we change the problem to one in which instead of the infinite set of energy levels (7) there is only a finite number of energy levels $E_n$. This is achieved, following a suggestion of Berry [5], by replacing the cylindrical phase space (with angular position $\theta$ periodic but angular momentum $L$ unbounded) by a torus on which both $\theta$ and $L$ are periodic. On quantization both $\theta$ and $L$ are discrete, and moreover, as we see, discrete times are also required. Adapting the methods used in section 2 to prove the Jacobi identity to this new setting, again two expressions for the trace of the quantum evolution operator are obtained, one by working in the momentum basis in which the evolution operator is diagonal and the other by path integral methods (using a novel discrete variant on Kelvin’s method of images); the equality of these two expressions gives the Landsberg-Schaar identity.

This first description of the discrete and cyclic path integral method is presented somewhat heuristically, but in a manner which should emphasise the ideas and motivation. In section 4 full details of the toroidal quantization are given together with a justification of the normalisations used in section 3.

2 Cylindrical phase space and the Jacobi identity

In this section earlier work of one of us [1] is described as a prelude to the main result of the paper, in order to demonstrate some of the novel features of the work.

Consider a rigid body constrained to rotate about a fixed axis (cf Schulman [3]). Let $I$ denote the moment of inertia and $\theta$ denote the angle of rotation (given in radians so that it is taken mod $2\pi$). An angular Schrödinger picture is used, with the angular momentum observable $L$ represented as the operator

$$L = -i\hbar \frac{\partial}{\partial \theta}$$

(where $\hbar$ as usual stands for Planck’s constant $h$ divided by $2\pi$). Using the classical expression for the energy or Hamiltonian

$$H = \frac{L^2}{2I},$$

the Schrödinger equation for the wave function $\psi(\theta, t)$ is then

$$i\hbar \frac{\partial \psi}{\partial t} = -\frac{\hbar^2}{2I} \frac{\partial^2 \psi}{\partial \theta^2}.$$
Suppose that $E_n$ denotes the $n^{th}$ eigenvalue of the quantized Hamiltonian with energy eigenfunction $\phi_n$,

$$-\frac{\hbar^2}{2I} \frac{\partial^2}{\partial \theta^2} \phi_n(\theta) = E_n \phi_n(\theta), \quad (6)$$

with respect to boundary values determined by periodicity in $\theta$ with period $2\pi$. Evidently

$$E_n = \frac{n^2 \hbar^2}{2I}, \quad \phi_n(\theta) = e^{in\theta}. \quad (7)$$

The solution of (6) satisfying the initial condition

$$\psi(\theta, 0) = \delta = \frac{1}{2\pi} \sum_{n=-\infty}^{+\infty} e^{in(\theta-\theta_0)}, \quad (8)$$

where $\delta$ denotes the periodic delta distribution with period $2\pi$ gives the kernel (or matrix element) of the evolution operator $\exp(-iHt/\hbar)$:

$$K(\theta, t; \theta_0, 0) = \langle \theta | e^{-iHt/\hbar} | \theta_0 \rangle = \frac{1}{2\pi} \sum_{n=-\infty}^{+\infty} e^{-\frac{\hbar n^2 t}{2I}} e^{in(\theta-\theta_0)}, \quad (9)$$

which is convergent in the distribution sense; alternatively one can give $t$ a small imaginary part to restore convergence. Later we shall see that when both position and momentum are cyclic, with phase space a torus, the problem of convergence does not arise.

From (9) we see that the trace of the evolution operator is

$$\text{Tr} \left( \exp(-iHt/\hbar) \right) = \frac{1}{2\pi} \sum_{n=-\infty}^{+\infty} e^{-\frac{\hbar n^2 t}{2I}} \quad (10)$$

with convergence in the sense described above.

Now, as in [1], we follow [8] adapted to the cylindrical phase space. The purpose of the section is to express the old idea of using the method of images and the universal cover of the circle in terms of path integrals, in such a way that the argument can be adapted to the toroidal phase space of section [9], obtaining a second expression for the trace of the evolution operator $\exp(iHt/\hbar)$ which on comparison with (10) gives the Jacobi identity.

Denote by

$$S(\theta(t)) = \int_0^t \mathcal{L}(\dot{\theta}, \theta; t) dt,$$  \quad (11)
the classical action, where $L$ is the Lagrangian, and then we obtain the evolution amplitude from $(\theta_0, 0)$ to $(\theta, t)$ as

$$K(\theta, t; \theta_0, 0) \sim \sum_{\text{periodic paths from } (\theta_0, 0) \text{ to } (\theta, t)} e^{iS(\theta)/\hbar}$$

where $\sim$ indicates that a normalisation factor (c.f. (13)) is required. In order to carry out the path integral sum we carry out the integration on the universal covering space, $\mathbb{R}$, of $S^1$, that is, we lift the homotopy classes to the universal covering space. Corresponding to paths from $\theta_0$ to $\theta$ in $S^1$, we have paths from some fixed $\theta^*_0$ in $\nu^{-1}(\theta_0)$ (here $\nu$ denotes the covering projection from $\mathbb{R}$ to $S^1$) to each of the $\theta^*_j$ in $\nu^{-1}(\theta)$, where the index $j$ runs through the fundamental group ($\cong \mathbb{Z}$) of $S^1$. It follows (this is of course Kelvin’s method of images) that

$$K(\theta, t; \theta_0, 0) = \sum_{n=-\infty}^{+\infty} \left( \frac{iI}{2\pi\hbar t} \right)^{1/2} \exp \left( \frac{iI}{2\hbar t} (\theta - \theta_0 - 2\pi n)^2 \right).$$

(13)

(The normalisation factor is taken from [8].)

On equating the expressions for the trace in (10) and (13) we obtain

$$\sum_{n=-\infty}^{+\infty} e^{\frac{i\hbar n^2 t}{2}} = \left( \frac{2\pi I}{\hbar t} \right)^{1/2} \sum_{n=-\infty}^{+\infty} e^{-\frac{2\pi^2 n^2 I}{\hbar t}}.$$  

(14)

(As already observed, care is needed over convergence, which is intended in the distributional sense.) If we arrange that $2\pi I = \hbar$, $\tau = it$, then we obtain formally the usual Jacobi identity (2) for $\vartheta(it)$.

After this work was presented [1] it was suggested by Berry [5] that the way forward to obtaining the Landsberg-Schaar formula by similar means might be to consider a system where the angular momentum, as well as the angle, was cyclic so that the phase space was compact and the quantized observables would not only be discrete but also have a finite range. This approach, which does indeed lead to the Landsberg-Schaar formula, is developed in the following section.

3 Toroidal phase space and the Landsberg-Schaar formula

In this section we adapt the methods of the preceding section to a toroidal phase space on which both $L$ and $\theta$ are periodic. On quantization this gives discreteness to
both these variables, and makes it possible (provided that suitable values are used for the various constants involved) to have only a finite number of energy eigenstates. Time, too, becomes quantized as emerges when evolution is considered. In this section we concentrate on ideas, obtaining the Landsberg-Schaar formula by proceeding in the manner of a physicist, while in the next section the quantization scheme is fully described and normalisation factors are derived.

Suppose that the phase space of our system is a torus, with angular momentum \( L \) of period \( P \) and angle of rotation \( \theta \) of period \( 2\pi \). Quantization in \( L \) and \( \theta \), when both \( \theta \) and \( L \) are periodic, gives, respectively:

\[
L = n\hbar, \quad \theta = \frac{2\pi nm}{P}, \quad m, n \in \mathbb{Z}.
\]  

The phase space is quantized to a lattice on the torus, and the small rectangles with sides \( \hbar \) and \( \frac{2\pi}{P} \) fit a whole number of times into the phase space torus area. The area of the phase space torus is \( 2\pi P \). So \( 2\pi P = 2\pi N\hbar \) (\( P = N\hbar, N \in \mathbb{Z} \)) and so the small rectangles fit \( N^2 \) times into the phase space torus.

There are precisely \( N \) energies, \( E_n, 1 \leq n \leq N \), and so the trace of the evolution operator is given by:

\[
\text{Tr}(\exp(-iHt/\hbar)) = \frac{1}{2\pi} \sum_{n=1}^{N} e^{-iE_nt/\hbar} = \frac{1}{2\pi} \sum_{n=1}^{N} e^{-i\hbar n^2 t/2}. \tag{16}
\]

Now we turn to the \( L \)-periodicity and show that it implies a restriction on the times, \( t \), of ‘looking at the system’.

Any quantum mechanical state \( \psi(\theta, t) \) has an expansion:

\[
\psi(\theta, t) = \sum_{k=-\infty}^{+\infty} a_k e^{i(k\theta - \frac{\hbar k^2 t}{2\hbar})}, a_k = a_{k+N} \tag{17}
\]

with the usual observations about convergence. Now take the Fourier transform in \( \theta \) of (17) to go from position (angle) space to momentum space. We obtain (here \( \hat{\psi} \) denotes the Fourier transform in the variable \( \theta \)),

\[
\hat{\psi}(L, t) = \int_{-\infty}^{+\infty} \psi(\theta, t) e^{-i\theta/\hbar} d\theta, \tag{18}
\]
and we use $\mathcal{F}[e^{ik\theta}] = \delta(L - kh)\)

$$\hat{\psi}(L, t) = \sum_{k=-\infty}^{+\infty} a_k e^{-\frac{ihk^2t}{2I}} \delta(L - kh), \quad (19)$$

where $\delta$ denotes the Dirac delta distribution, and

$$\hat{\psi}(L, t) = \sum_{k=-\infty}^{+\infty} a_k e^{-\frac{ihk^2t}{2I}} \delta(L + P - kh)$$

$$= \sum_{k=-\infty}^{+\infty} a_k e^{-\frac{ih(k+\frac{N}{2})^2t}{2I}} \delta(L - kh). \quad (20)$$

Thus periodicity of period $P$ in $L$, that is $\hat{\psi}(L + P, t) = \hat{\psi}(L, t)$, implies

$$1 = e^{-ih(N^2+2kN)/(2I)} \quad (21)$$

so that (assuming $N$ is even, as is required later)

$$t = \frac{2\pi mI}{Nh}, \quad m \in \mathbb{Z}. \quad (22)$$

On substituting from (22) in (16) we obtain

$$\text{Tr}(\exp -iHt/h) = \frac{1}{2\pi} \sum_{n=0}^{N} e^{-i\pi 2m^2/2I}$$

$$= \frac{1}{2\pi} \sum_{n=0}^{N} e^{-i\pi n^2/\pi}. \quad (23)$$

We have to compute

$$\sum_{\text{periodic paths}} e^{iS(\theta)/h}, \quad (24)$$

where the sum is now over all periodic paths on the torus. At the $n^{th}$ energy level, $p_n$ is constant:

$$E_n = \frac{p_n^2}{2I}, I\dot{\theta}_n = p_n, I\theta = p_n t. \quad (25)$$

Hence, for the ‘time of looking’ given in (22),

$$|I\theta| \leq p_n \cdot \frac{2|m|\pi I}{Nh} \leq |m| \cdot 2\pi I. \quad (26)$$
On repeating the argument given in section 2, but now restricting \( \theta \) as in (26), we obtain in place of (13)

\[
K(\theta, t) = m^{-1} \sum_{n=0}^{m-1} \left( \frac{I}{2\pi i\hbar t} \right)^{\frac{1}{2}} \exp \left( \frac{iI}{\hbar t} (\theta - 2\pi n)^2 \right),
\]

(27)

where as before

\[
t = \frac{2\pi mI}{N\hbar}.
\]

(28)

(The normalisation factor used is taken from (13), and is justified in section 4; while it might seem simpler to derive this by the method used by Davison [9] than by the methods of section 4, in fact there is a crucial step (equation (3.5) of Davison’s paper) which would require knowledge of the Gauss sums under study.)

It follows from (27) that the propagator trace is

\[
\text{Tr}(\exp -iHt/\hbar) = \left( \frac{N}{4\pi^2 im} \right)^{\frac{1}{2}} \sum_{n=0}^{m-1} \left( \frac{in^2}{2\hbar^2 m n} \right)\exp \left( \frac{in^2}{2\hbar^2 m n} \right)
\]

\[
= \left( \frac{N}{im} \right)^{\frac{1}{2}} \sum_{n=0}^{m-1} e^{i\pi n^2 N/m}.
\]

(29)

So, on equating (16) and (29), we obtain

\[
\sum_{n=0}^{N} e^{-2\pi n^2 / N} = \left( \frac{N}{im} \right)^{\frac{1}{2}} \sum_{n=0}^{m-1} e^{i\pi n^2 N/m}.
\]

(30)

Finally in (30) we take \( N = 2q, m = p, i^{-1} = -e^{\pi i/2} \) to obtain

\[
\frac{e^{\pi i/4}}{\sqrt{(2q)}} \sum_{n=0}^{2q-1} \exp \left( -\frac{\pi in^2 p}{2q} \right) = \frac{1}{\sqrt{p}} \sum_{n=0}^{p-1} \exp \left( \frac{2\pi in^2 q}{p} \right),
\]

(31)

which is the Landsberg-Schaar formula (1).

4 Normalisation of the discrete path integral

In this section details are given of the quantum mechanical system whose path integration is used in the previous section to prove the Landsberg-Schaar formula (1).
The necessary path integral formula is derived by adapting the original approach of Feynman [8] to the discrete and cyclic setting. Because all sums are finite in this case there are no convergence or other analytic difficulties, so that a precise result is obtained with well-defined normalisation. This confirms the validity of the more heuristic, but geometrically and arithmetically well-motivated, use of the Feynman principle in the previous section.

The starting point is the classical phase space of the system, which is taken to be toroidal with coordinates $\theta, L$ of periodicity $2\pi$ and $P$ respectively. As Hilbert space for our system we take $\mathcal{H} = \mathbb{C}^N$ (where $N$ is a positive integer) realised as

$$\left\{ f : \mathbb{R} \to \mathbb{C} | f(\theta) = \sum_{n=1}^{N} a_n \exp \left( \frac{2\pi i n \theta}{N} \right) \right\}$$

where each $a_n$ is a complex number.

One basis of $\mathcal{H}$ is then plainly $\{ f_k : k = 0, \ldots, N - 1 \}$ with $f_k(\theta) = \frac{1}{\sqrt{N}} \exp \left( \frac{2\pi i k \theta}{N} \right)$. This is the angular momentum basis, that is, each $f_k$ is an eigenvector of the angular momentum operator $L$ (defined now by $L = -i \frac{N}{2\pi} \frac{\partial}{\partial \theta}$) with eigenvalue $k$. Using Dirac notation, we write $f_k$ as $|k\rangle$. For simplicity we use units in which $\hbar$ takes the value 1.

Another basis is $\{ b_r : r = 1, \ldots, N \}$ with

$$b_r(\theta) = \frac{1}{N} \sum_{k=0}^{N-1} \exp \left( \frac{2\pi i (\theta - r) k}{N} \right). \quad (32)$$

The inner product on $\mathcal{H}$ is defined by

$$\langle f | g \rangle = \sum_{j=0}^{N-1} f(j)^* g(j). \quad (33)$$

With this inner product both of these bases are orthonormal.

The $b_r$ may be regarded as the position basis if one restricts the domain of the elements $f$ of $\mathcal{H}$ to $\mathbb{Z}_N = \{ 0, 1, \ldots, N - 1 \}$ and defines the (exponentiated angular) position operator $\hat{x}$ by

$$\hat{x} f(\theta) = \exp \left( 2\pi i \frac{\theta}{N} \right) f(\theta), \quad (34)$$

since then

$$\hat{x} b_r = \exp \left( 2\pi i \frac{r}{N} \right) b_r \quad (35)$$

so that $b_r$ is an eigenstate of $\hat{x}$, with eigenvalue $\exp \left( 2\pi i \frac{r}{N} \right)$. (In Dirac notation we write $b_r$ as $|r\rangle$.)

9
Now the proof of the Landsberg-Schaar identity essentially involves calculating the trace of $\exp -iHt$ (with $H = \frac{L^2}{2\hbar}$ and $t = \frac{2\pi m\hbar}{N}$ as before) in these two different bases. From the outset we will set $m = p$, where $p$ is one of the two integers in the Landsberg-Schaar formula.

Method 1 is the direct way, that is, working in the momentum basis in which $H$ is diagonal.

We have $H|k\rangle = \frac{\pi k^2 p}{N} |k\rangle$ so that

$$\text{Tr} \left( \exp -iHt \right) = \sum_{k=0}^{N-1} \exp \left( -\frac{i\pi k^2 p}{N} \right)$$  \hspace{1cm} (36)

Method 2 uses discrete, cyclic ‘path integrals’. We consider $\langle r | \exp -iHt | s \rangle$.

Breaking the time interval into $p$ steps $\Delta t = \frac{t}{p}$, and using $s_i$ to label basis elements $b_{s_i}$ at the $i^{th}$ step, we have

$$\langle r | \exp -iHt | s \rangle = \langle r | \exp -iH\Delta t | s_{p-1} \rangle \langle s_{p-1} | \exp -iH\Delta t | s_{p-2} \rangle \cdots \langle s_1 | \exp -iH\Delta t | s \rangle$$  \hspace{1cm} (37)

(with summation from 0 to $N-1$ over each of the intermediate $s_i, i = 1, \ldots, p-1$). We thus need to consider $\langle s_i | \exp -iH\Delta t | s_{i-1} \rangle$. Now

$$\langle s_i | \exp -iH\Delta t | s_{i-1} \rangle = \sum_{k=0}^{N-1} \langle s_i | k \rangle \langle k | s_{i-1} \rangle \exp \left( -\frac{\pi ik^2}{N} \right)$$

$$= \sum_{k=0}^{N-1} \frac{1}{N} \exp \left( \frac{2\pi ik(s_i - s_{i-1})}{N} \right) \exp \left( -\frac{\pi ik^2}{N} \right)$$  \hspace{1cm} (38)

(using the fact that

$$\langle r | k \rangle = \frac{1}{\sqrt{N}} \exp \left( \frac{2\pi kr}{N} \right).$$  \hspace{1cm} (39)

Thus

$$\langle s_i | \exp -iH\Delta t | s_{i-1} \rangle = \sum_{k=0}^{N-1} \frac{1}{N} \exp \left( -\frac{\pi i}{N} (k - (s_i - s_{i-1}))^2 \right) \exp \left( \pi i \frac{(s_i - s_{i-1})^2}{N} \right).$$  \hspace{1cm} (40)
Again, as in section 3, we set \( N = 2q \), so that in particular \( N \) is even and we have

\[
\langle s_i | \exp -iHT | s_{i-1} \rangle = \sum_{k=0}^{N-1} \frac{1}{N} \exp \left( -\frac{2\pi i}{2N} (k - (s_i - s_{i-1}))^2 \right) \exp \left( 2\pi i \frac{(s_i - s_{i-1})^2}{2N} \right)
\]

\[
= \frac{1}{\sqrt{iN}} \exp \left( 2\pi i \frac{(s_i - s_{i-1})^2}{2N} \right)
\]

by equation (50) of the appendix. Thus

\[
\langle r | \exp -iHT | s \rangle = (iN)^{-p/2} \sum_{s_1=0}^{N-1} \ldots \sum_{s_{p-1}=0}^{N-1} \exp \left( 2\pi i \sum_{i=1}^{p} (s_i - s_{i-1})^2 \right)
\]

where \( s_0 = r, s_p = s \).

At this stage we assume that \( p \) and \( q \) are coprime. Then, if \( p \) is odd, so that \( p \) and \( N = 2q \) are coprime, we may observe that

\[
\sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(kN + lp)^2}{2Np} \right) = \sum_{l=0}^{N-1} \exp \left( \frac{2\pi i l^2}{2Np} \right) = \sqrt{iNp}
\]

where we have used the result (49) from the appendix. (Because \( p \) and \( N \) are coprime the expression \( kN + lp \) takes all \( Np \) distinct values (mod\( Np \)) as \( k \) ranges from 0 to \( p - 1 \) and \( l \) ranges from 0 to \( N - 1 \).) Also, if \( p = 2r \) is even (but \( p \) and \( q \) are still coprime) then

\[
\sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(kN + lp)^2}{2Np} \right) = \sum_{l=0}^{2q-1} \sum_{k=0}^{2r-1} \exp \left( 2\pi i \frac{(kq + lr)^2}{2qr} \right) = \sqrt{(1 + (-1)^r)iNp}.
\]

This result allows us to insert in the expression for \( \langle r | \exp -iHt | s \rangle \) the extra summations \( \sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(kN + lp)^2}{2Np} \right) \) together with the compensating factor \( 1/\sqrt{iNp} \) (if \( p \) is odd) or \( 1/\sqrt{2iNp} \) (if \( p = 2r \) with \( r = 2r' \) even). We can overlook the case where \( p = 2r \) and \( r \) is odd, since in that case the Landsberg-Schaar equation is trivially satisfied. This step effectively allows the winding number \( k \) for a path to be shared over the \( p \) steps in the path.

Using these facts, we see that if \( p \) and \( q \) are coprime and \( a = 1 \) when \( p \) is odd while \( a = 2 \) when \( p = 4r' \),

\[
\langle r | \exp -iHt | s \rangle
\]
\begin{align*}
&= \frac{(iN)^{-p/2}}{\sqrt{iaNp}} \sum_{s_1 = 0}^{N-1} \cdots \sum_{s_{p-1} = 0}^{N-1} \sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \left( \sum_{i=1}^{p} \frac{(s_i - s_{i-1})^2}{2N} + \frac{(kN + lp)^2}{2Np} \right) \right) \\
&= \frac{(iN)^{-p/2}}{\sqrt{iaNp}} \sum_{s_1 = 0}^{N-1} \cdots \sum_{s_{p-1} = 0}^{N-1} \sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \left( \sum_{i=1}^{p} \frac{(s_i - s_{i-1})^2}{2N} + \frac{l^2}{2N} + \frac{(k^2q)}{p} \right) \right) \\
&= \frac{(iN)^{-p/2}}{\sqrt{iaNp}} \sum_{s_1 = 0}^{N-1} \cdots \sum_{s_{p-1} = 0}^{N-1} \sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \left( \sum_{i=1}^{p} \frac{(s_i - s_{i-1} + l)^2}{2N} + \frac{(k^2q)}{p} \right) \right) \\
&= \frac{(iN)^{-p/2}}{\sqrt{iaNp}} \sum_{s_1 = 0}^{N-1} \cdots \sum_{s_{p-1} = 0}^{N-1} \sum_{l=0}^{N-1} \sum_{k=0}^{p-1} \exp \left( 2\pi i \left( \sum_{i=1}^{p} \frac{(s_i - s_{i-1} + l)^2}{2N} + \frac{(k^2q)}{p} \right) \right) \\
&\quad \text{by (49)} \\
&= \frac{1}{\sqrt{ipN}} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(k^2q)}{p} \right), \quad (46)
\end{align*}

provided that \(r - s \equiv 0 \pmod N\).

Now let \(u_1 = s_1 - s_0 + l = s_1 - r + l, u_2 = s_2 - s_1 + l\) and so on, with \(u_p = s_p - s_{p-1} + l = s - s_{p-1} + l\). Then \(\sum_{i=1}^{p} u_i = r - s + lp\) so that \(u_p = r - s + lp - \sum_{i=1}^{p-1} i_i\).

Thus if \(p\) and \(N\) are coprime and \(s_1, \ldots, s_{p-1}\) are fixed the integer variable \(u_p\) will take each value 0, 1, \ldots, \(N - 1 \pmod N\) precisely once as \(l\) ranges from 0 to \(N - 1\), so that

\begin{align*}
\langle r | \exp (-iHT) | s \rangle & = \frac{(iN)^{-p/2}}{\sqrt{iaNp}} \sum_{u_1 = 0}^{N-1} \cdots \sum_{u_p = 0}^{N-1} \exp \left( 2\pi i \left( \sum_{i=1}^{p} \frac{u_i^2}{2N} \right) \right) \exp \left( 2\pi i \frac{(k^2q)}{p} \right) \\
&= \frac{(iN)^{-p/2}}{\sqrt{iaNp}} (Ni)^{p/2} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(k^2q)}{p} \right) \text{ by (49)} \\
&= \frac{1}{\sqrt{ipN}} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(k^2q)}{p} \right), \quad (46)
\end{align*}

Hence

\begin{align*}
\text{Tr} (\exp iHt) &= \sum_{s=0}^{N-1} \langle s | \exp iHt | s \rangle \\
&= \frac{N}{\sqrt{ipN}} \sum_{k=1}^{p} \exp \left( 2\pi i \frac{(k^2q)}{p} \right) \\
&= \frac{\sqrt{2\pi q}}{\sqrt{ip}} \sum_{k=1}^{p} \exp \left( 2\pi i \frac{(k^2q)}{p} \right) \quad \text{(since } N = 2q\text{).} \quad (47)
\end{align*}
(If \( p = 4r' \) with \( p \) and \( q \) still coprime, then the values of \( u_r \) are restricted, so that summation over \( l \) contributes a factor \( \exp \left( \frac{u^2}{2N} \right) = \sqrt{2iNp} \). The result above is thus also obtained in this case.)

Hence in all cases when \( p \) and \( q \) are coprime we have (using (36),
\[
\sum_{k=0}^{2q-1} \exp \left( -\pi i k^2 p \right) = \frac{\sqrt{2q}}{\sqrt{ip}} \sum_{k=0}^{p-1} \exp \left( 2\pi i \frac{(k^2 q)}{p} \right)
\]
which immediately gives the Landsberg-Schaar formula when \( p \) and \( q \) are coprime. The general case follows on setting \( p = mp' \), \( q = mq' \) with \( p', q' \) coprime.

**Appendix**

The two formulae below may be proved by elementary means: [10, 11]
\[
\sum_{n=0}^{2r-1} \exp \left( \frac{2\pi i (n-s)^2}{4r} \right) = \sqrt{2ri}
\]
\[
\sum_{k=0}^{2r-1} \exp \left( -2\pi i \frac{(k-s)^2}{4r} \right) = \sqrt{\frac{2r}{i}}
\]

Given such an elementary evaluation of the Gauss sum, together with an elementary proof of the quadratic reciprocity law
\[
\left( \frac{p}{q} \right) \left( \frac{q}{p} \right) = (-1)^{\frac{p-1}{2} \cdot \frac{q-1}{2}},
\]
where \( \left( \frac{p}{q} \right) \) denotes the Legendre symbol and \( p \) and \( q \) are odd primes, one could prove [11] by evaluating each side and then appealing to the reciprocity law, and its extensions (to \( p = 2 \) and \( p = -1 \)). Whether such a proof would provide insight into why the result is true is another matter.

Again, there is another proof of the theta function identity (2), due to Polya [12], which depends on an identity involving binomial coefficients, identities which are in turn related to the Markov chain approach to diffusion processes considered in [1].

The approach adopted in this paper presupposes an elementary proof of the evaluation of Gauss sums in (49) and (50), but not of the reciprocity law. It is perhaps tempting therefore to regard the present approach as a substitute, in some sense, to the reciprocity law, but we prefer to see it as a quantum mechanical equivalent of Hecke’s observation, in which Feynman’s ‘sum over histories’ in discrete time replaces the limiting process that derives [11] from (2).
