Abstract: Ceria (CeO₂) nanoparticles have been widely studied for numerous applications, but only a few recent studies have investigated their potential applications in medicine. Moreover, there have been almost no studies focusing on their possible antibacterial properties, despite the fact that such nanoparticles may reduce reactive oxygen species. In this study, we coated CeO₂ nanoparticles with dextran or polyacrylic acid (PAA) because of their enhanced biocompatibility properties, minimized toxicity, and reduced clearance by the immune system. For the first time, the coated CeO₂ nanoparticles were tested in bacterial assays involving *Pseudomonas aeruginosa*, one of the most significant bacteria responsible for infecting numerous medical devices. The results showed that CeO₂ nanoparticles with either coating significantly inhibited the growth of *Pseudomonas aeruginosa*, by up to 55.14%, after 24 hours compared with controls (no particles). The inhibition of bacterial growth was concentration dependent. In summary, this study revealed, for the first time, that the characterized dextran- and PAA-coated CeO₂ nanoparticles could be potential novel materials for numerous antibacterial applications.

Keywords: antibacterial, biomedical applications

Introduction

Among the rare earth elements (the 15 lanthanides, along with scandium and yttrium), cerium is the most abundant element, at 66.5 ppm in the Earth’s crust compared with copper (60 ppm) or tin (2.3 ppm).³,¹² As a highly abundant material, ceria (or cerium oxide [CeO₂]) is technologically important due to its wide range of applications, for example, in catalysts for the elimination of toxic auto exhaust gases,⁴,⁵ oxygen sensors,⁵,⁶ fuel cells,⁷–⁹ electrochromic thin films,¹⁰,¹¹ and so on. Upon the transition from a macroporous particle to a nanocrystalline particle, CeO₂ significantly changes its physicochemical properties to, usually, possess a high density of nanocrystalline CeO₂ interfaces.¹² Thus, nanostructured CeO₂ has attracted extensive attention in the field of nanotechnology due to improvements in redox properties, transport properties, and high surface to volume ratios, which may be of value for various biological applications.

However, although CeO₂ nanoparticles have been studied for numerous traditional scientific and engineering applications, there have been almost no studies regarding the potential biomedical applications of CeO₂ until recently, when researchers demonstrated that CeO₂ nanoparticles possess antioxidant properties at physiological pH values. The ability of these nanoparticles to act as an antioxidant lies in their ability to reversibly switch from Ce³⁺ to Ce⁴⁺.¹³ In recent studies, this antioxidative ability enabled the application of CeO₂ nanoparticles to protect against radiation damage, oxidative stress, and inflammation.¹⁴–¹⁶ For example, Tsai et al reported
that free radical scavenging could be achieved in murine insulinoma βTC-tet cells by the introduction of crystalline CeO$_2$ nanoparticles.\textsuperscript{17}

Moreover, in previous studies, due to safety concerns for biomedical applications, the toxicity of zinc oxide (ZnO), CeO$_2$, and titanium oxide (TiO$_2$) was compared based on dissolution and oxidative stress properties.\textsuperscript{18,19} The results showed that the CeO$_2$ nanoparticles could suppress the generation of reactive oxygen species (ROS) and induce cellular resistance to an exogenous source of oxidative stress, to protect cells from oxidation injury. However, concerns over CeO$_2$ toxicity, biocompatibility, and avoidance of immune-system clearance remained. Thus, to further improve the clinical use of CeO$_2$ nanoparticles, previous efforts have coated CeO$_2$ with biocompatible dextran and PAA; enhanced stability in aqueous solutions has also been reported for these coated CeO$_2$ nanoparticles.\textsuperscript{15,31}

To build on these exciting medical applications of CeO$_2$ nanoparticles, the present study investigated, for the first time, the influence of dextran- and PAA-coated CeO$_2$ nanoparticles on bacterial growth. Pseudomonas aeruginosa is an aerobic gram-negative bacterium that is an important cause of various infections, especially in hospitals. Hospitalized patients may be colonized with P. aeruginosa on admission or during their hospital stay, and P. aeruginosa can be isolated from nearly any conceivable source within hospitals.\textsuperscript{20,21} It accounts for $11\% - 13.8\%$ of all nosocomial infections when a microbiological isolate is identifiable.\textsuperscript{22} Infections caused by P. aeruginosa are not only common,\textsuperscript{23,24} but are also associated with high morbidity and mortality when compared with other bacterial pathogens.\textsuperscript{25,26} An additional concern involves the increased antimicrobial resistance of nosocomial P. aeruginosa isolates.\textsuperscript{27} Even more troublesome, P. aeruginosa attaches to both biotic and abiotic surfaces, forming a biofilm. Once formed, the P. aeruginosa infections are much more difficult to treat, due to their formation of exopolysaccharides. Biofilms of P. aeruginosa have been found on numerous medical devices, including central venous catheters, contact lenses, mechanical heart valves, intrauterine devices, and indwelling urinary catheters.\textsuperscript{28,29} Thus, it is significant to develop active and biocompatible molecules that do not rely on antibiotics, to which bacteria may develop a resistance, and that kill bacteria at early stages of infections, before biofilm formation.

Therefore in this study, for the first time, due to concerns over the biocompatibility, toxicity, and immune system clearance of pristine CeO$_2$ nanoparticles, we investigated the effectiveness of dextran- and PAA-coated CeO$_2$ nanoparticles in inhibiting bacterial growth, specifically, P. aeruginosa. The results showed that such coated CeO$_2$ nanoparticles significantly inhibited the growth of P. aeruginosa, revealing a promising application of CeO$_2$ nanoparticles to prevent bacterial infections that should be further explored.

**Materials and methods**

**Synthesis, coating, and characterization of the cerium oxide nanoparticles**

The dextran- or PAA-coated CeO$_2$ nanoparticles were synthesized according to previously described procedures.\textsuperscript{15,30,31} Briefly, a solution of cerium (III) nitrate (1.0 M, 99\%) (Sigma-Aldrich Corp, St Louis, MO, USA) in water (5.0 mL) was mixed with an aqueous solution of either PAA (0.5 M) (Sigma-Aldrich Corp) or dextran (1.0 M) (Sigma-Aldrich Corp). The resulting mixtures were then added to an ammonium hydroxide solution (30.0 mL, 30\%) (Sigma-Aldrich Corp) under continuous stirring for 24 hours, at room temperature. The preparation was then centrifuged at 4000 rpm for two 30-minute cycles to settle down any debris and large agglomerates. The supernatant solution was then purified from free polymers and other reagents and then concentrated using a 30K Amicon® Ultra-4 Centrifugal Filter Units (EMD Millipore Corp, Billerica, MA, USA). The final dextran- and PAA-coated CeO$_2$ nanoparticle preparations were stored at a 1.5 mg CeO$_2$/mL concentration in deionized water until further used; such concentrations have previously been shown to be nontoxic to mammalian cells.\textsuperscript{15,30,31}

The various polymer-coated CeO$_2$ nanoparticle preparations were characterized by dynamic light scattering (DLS) to determine the size, zeta potential, and surface charge of the nanoparticles (Zetasizer; Malvern Instruments Ltd, Malvern, UK). Fourier transform infrared (FTIR) spectrometry analysis was performed on vacuum dried samples to verify the surface functionalities of the nanoparticles (Spectrum™ 100 Optica; PerkinElmer Inc, Waltham, MA, USA).

**Bacterial assays**

A bacteria cell line of P. aeruginosa was obtained in freeze-dried form from the American Type Culture Collection (catalog number 27853; Manassas, VA, USA). The bacterial cells were propagated in 30 mg/mL tryptic soy broth (TSB) (catalog number 22092; Sigma-Aldrich Corp) for 24 hours in an incubator (37°C, humidified, 5% carbon dioxide). When the second passage of bacteria reached its stationary phase,
the second passage was frozen in one part TSB and one part 40% sterile glycerol (catalog number G5516; Sigma-Aldrich Corp). Before bacterial seeding, a sterile 10 µL loop was used to withdraw bacteria from the prepared frozen stock, the bacteria were streaked onto a TSB Agar plate (catalog number A1296; Sigma-Aldrich Corp), and the TSB agar plate was incubated for 20 hours, to form single bacterial colonies. Then, a single colony was collected using a sterile loop and was incubated in a 15 mL sterile test tube containing 3 mL of TSB, for 20 hours. The bacterial solution was diluted to a concentration of 10^7 bacteria/mL, which was assessed by measuring the optical density of the bacterial solution, using a standard curve correlating optical densities and bacterial concentrations. The optical densities were measured at 562 nm, using a SpectraMax M5 Microplate Reader (Molecular Devices LLC, Sunnyvale, CA, USA).

Two concentrations of both dextran- or PAA-coated CeO₂ nanoparticles were separately tested against bacterial growth. The solutions of CeO₂ nanoparticles were mixed with bacterial solutions (10^7 bacteria/mL) at a 1:10 or 1:5 volume ratio and cultured for either 1, 6, or 24 hours in the incubator. Solutions of sterile TSB were mixed with bacteria solutions as blank controls. After the treatment, the solutions with bacteria were diluted with a phosphate-buffered saline (PBS) (catalog number P4417; Sigma-Aldrich Corp) solution and were spread on agar plates, and the bacteria colonies were counted after 18 hours of incubation.

Bacterial tests were conducted in triplicate and repeated three times. Data were collected, and the differences were assessed with the probability associated with a one-tailed Student’s t-test. Statistical analyses were performed using Microsoft® Excel® 2010 (Microsoft Corporation, Redmond, WA, USA).

Results and discussion

Cerium oxide nanoparticle characterization

The CeO₂ nanoparticle preparations used in this study were aqueous suspensions of nanoparticles coated with either PAA or dextran. The synthetic procedure used to make these nanoparticles is highly reproducible and yielded nanoparticles with a CeO₂ core of 3–4 nm, by transmission electron microscopy (TEM). Specifically, the hydrodynamic diameter of the PAA-coated CeO₂ nanoparticles was 5 nm, while the size for the dextran-coated CeO₂ nanoparticles was 14 nm. Confirmation of the polymer coating was accessed by FTIR, as previously described, and by zeta potential, confirming the presence of a highly negative charged polymer coating for the PAA-coated CeO₂ nanoparticles (ζ = −45 mV) and a lower negative charge (close to neutral) for the dextran-coated CeO₂ nanoparticles (ζ = −2 mV).

Bacterial assays

As shown in Figures 1 and 2, the CeO₂ nanoparticles did not show significant inhibition of P. aeruginosa growth compared with the TSB controls after 1 hour of treatment. However, after 6 hours of treatment, both concentrations of the dextran-coated CeO₂ nanoparticles were found to have significantly inhibited the growth of P. aeruginosa, by about 20% compared with the TSB controls (P < 0.05). The PAA-coated CeO₂ nanoparticles showed significant inhibition of P. aeruginosa growth only for the higher concentration (bacterial solution:CeO₂ nanoparticles = 5:1).

Most importantly, the growth of P. aeruginosa was strongly inhibited in the presence of either the dextran- or PAA-coated CeO₂ nanoparticles after 24 hours compared...
with the TSB controls ($P < 0.01$). When the volume ratio of bacterial solution to CeO$_2$ nanoparticles was 10:1, $P$. aeruginosa growth was inhibited by 40.12% and 26.88% in the presence of dextran- and PAA-coated CeO$_2$ nanoparticles, respectively, compared with the TSB controls. When the concentration of CeO$_2$ nanoparticles doubled, the inhibition of $P$. aeruginosa growth reached 55.41% and 36.44% for the dextran- and PAA-coated CeO$_2$ nanoparticles, respectively. Critically, all of this inhibition occurred without the use of antibiotics, with only the use of the CeO$_2$ nanoparticles.

Based on the results of bacterial assays, the inhibition to $P$. aeruginosa growth by dextran- and PAA-coated CeO$_2$ nanoparticles was more significant as the treatment time increased to 24 hours. In addition, the dextran-coated CeO$_2$ nanoparticles showed a stronger inhibition of bacterial growth than did the PAA-coated CeO$_2$ nanoparticles, especially after treatment for 6 and 24 hours. One possible reason the dextran coating and PAA coating could affect the bacterial growth differently is that the size of the dextran-coated CeO$_2$ nanoparticles was 14 nm and the size of PAA-coated CeO$_2$ nanoparticles was 5 nm, which translates to an altered ability to interact with bacteria membranes. In addition, as mentioned, the surface energy of the dextran- and PAA-coated CeO$_2$ nanoparticles was different, which could also have strongly influenced their interactions with bacteria cell membranes. Moreover, as expected, from 6 hours to 24 hours, the bacteria propagated quickly in the TSB control, but the bacteria numbers decreased even more during this time period with the treatment with both kinds of coated CeO$_2$ nanoparticles.

Importantly, the mechanism of how dextran- and PAA-coated CeO$_2$ nanoparticles prevented bacterial growth remains unexplored. Since CeO$_2$ nanoparticles have been shown to suppress the generation of ROS, their antibacterial properties demonstrated here, for the first time, could be different from those of many other nanoparticles (such as ZnO nanoparticles, silver [Ag] nanoparticles, and so on) that are believed to kill bacteria mainly through the generation of ROS. Although requiring additional investigation, the possible mechanism for the antibacterial action of the coated CeO$_2$ nanoparticles formulated here could be that the dextran and PAA coatings interacted with specific proteins on the bacterial cell membranes to alter the permeability of the cell membranes, thus, killing the bacterial cells. Moreover, it is possible that the dextran or PAA coated CeO$_2$ nanoparticles studied here may have promoted the adsorption, from the TSB, of proteins that are known to inhibit bacteria growth (such as fibronectin, mucin, vitronectin, etc).

Future studies should also investigate how universal such bacterial inhibition is, by exposing such coated CeO$_2$ nanoparticles to other bacteria (such as Staphylococcus aureus and Escherichia coli).

**Conclusion**

In conclusion, the growth of $P$. aeruginosa was significantly inhibited in the presence of either dextran- or PAA-coated CeO$_2$ nanoparticles after 24 hours. The effectiveness of bacterial-growth inhibition reached 55.41% for the dextran-coated CeO$_2$ nanoparticles compared with the TSB control. This study revealed, for the first time, that the characterized coated CeO$_2$ nanoparticles could potentially serve as a novel antibacterial agent in biomedical applications. Further studies, such as investigation of longer-term treatment and elucidating the mechanism of action, are important
to achieve a better understanding and the application of such coated CeO$_2$ nanoparticles in numerous antibacterial applications.
