Pulmonary alveolar microlithiasis (PAM) is an uncommon disorder characterized by calcium phosphatase crystals deposition into the alveoli. PAM was described for the first time by Marcello Malpighi in 1868, and the histopathology was detailed by Harbitz in 1918. PAM is caused by a mutation in the SLC34A2 gene encoding the type IIb sodium phosphate cotransporter in alveolar type II cells. This results in the formation and accumulation of calcium phosphates crystals in the alveoli. Early in the disease, most patients are asymptomatic or might experience mild symptoms. However, in some patients, PAM can progress resulting in pulmonary fibrosis, cor pulmonale, and respiratory failure. We report the case of a 33-year-old Omani male who was referred to our institute with a history of fever and shortness of breath. A chest radiograph revealed bilateral dense consolidation. Chest computed tomography showed bilateral dense interlobular thickening and extensive consolidations with a lower lung predominance. Our findings were highly suggestive of PAM. The diagnosis was confirmed by bronchoalveolar lavage.

A 33-year-old Omani male presented to a local health center for the first time in July 2017 with a one-week history of fever and shortness of breath. The patient was then referred to our institute, Royal Hospital, Muscat, for further workup. Upon arrival, the patient was afebrile (36.4 °C). However, he was sick looking and tachypneic. His respiratory rate was 44 with a high blood pressure (150/100 mmHg). His saturation was 75% in room air. On auscultation, he had bilateral crepitation. Laparotomy examinations showed high C-reactive protein (52 mg/L). Arterial blood gas analysis showed: pH 7.33, carbon dioxide partial pressure 62 mmHg, oxygen partial pressure 83 mmHg, and fraction of inspired oxygen 100. His complete blood count was normal, and his white blood cell count was 9.4 × 10⁹/L (normal range: 7.2–10.5 × 10⁹/L), blood platelet count was 243 × 10⁹/L (normal range: 140–400 × 10⁹/L), hemoglobin levels were 14.4 g/dL (normal range: 11.5–15.5 g/dL), calcium was 2.33 mmol/L (normal range: 2.1–2.55 mmol/L), corrected calcium for albumin was 2.59 mmol/L (normal range: 2.1–2.6 mmol/L), phosphate was 0.84 mol/L (normal range: 0.75–1.5 mol/L), and parathyroid was 2.9
pmol/L (normal range: 1.6–6.9 pmol/L). Other lab investigations were within normal limits including renal and liver function tests. A chest radiograph was performed and revealed bilateral dense consolidation [Figure 1].

The impression was severe lower respiratory tract infection complicated by acute respiratory distress syndrome (ARDS). The patient was electively intubated and admitted to the intensive care unit. Septic workup including respiratory viral panel, human immunodeficiency virus, sputum, urine, and blood cultures were negative. Sputum was negative for acid-fast bacilli. Further evaluation of chest radiograph findings with high-resolution computed tomography (HRCT) of the chest showed bilateral dense interlobular thickening and extensive consolidations with a calcific density distributed bilaterally throughout both lung fields with a lower lobe predominance [Figure 2], findings were highly suggestive of PAM. To confirm the diagnosis, bronchoscopy and bronchoalveolar lavage were performed. Mycobacterium tuberculosis culture was negative, and no other pathogens were isolated. Histopathological examination showed cellular smears composed of scattered lamellar microliths accompanied by many foamy macrophages and some bronchial epithelial cells [Figure 3]. The findings were consistent with the diagnosis of PAM. The patient continued to be treated as a lower respiratory tract infection and made a full recovery. However, he continues to complain of shortness of breath on exertion. The treatment for PAM is lung transplant. However, lung transplant was not feasible in our patient, and we chose to treat him symptomatically. The patient had genetic counseling, but no genetic testing was done as the test was not available.

**DISCUSSION**

PAM is a rare hereditary disease of the lung that is characterized by a chronic intra-alveolar accumulation of microliths. It is caused by a mutation in the *SLC34A2* gene encoding type IIb sodium phosphate cotransporter in alveolar type II cells.
This leads to reduced uptake of phosphate, which causes the formation of intra-alveolar microliths as a result of phosphate chelating calcium in extracellular fluid. Although PAM can affect all age groups, most of the affected patients are in their second and third decades of life. PAM has a slight male predominance, and only 37% of patients have a positive family history of PAM. Our patient was an Omani male in his third decade of life with no family history of PAM.

Early in the disease, patients with PAM are either asymptomatic or might experience mild symptoms such as non-productive cough or shortness of breath. After the diagnosis, the course of the disease varies, while in a few patients the radiological findings and symptoms remain stable. The majority of patients have a slowly progressive course that eventually ends into pulmonary fibrosis, cor pulmonale, and respiratory failure.

The diagnosis of PAM is usually established by identifying the typical radiological and histopathological features. Radiological findings depend on the severity of the disease. On chest radiographs, patients with PAM usually have bilateral, sand-like micronodules of calcific density with a sandstorm appearance.
predominantly in the mid and lower lung zones.\(^2\)\(^3\) On HRCT, more subtle findings can be detected, which might not be best appreciated on the chest radiograph. Early in the disease, bilateral non-calciﬁed micronodules can be seen in the HRCT of asymptomatic children with PAM. As the disease progresses, there are usually bilateral innumerable calciﬁed micronodules (< 1 mm) distributed throughout both lung ﬁelds with predominant involvement of the mid to lower lung zones and posterior basal segments.\(^3\)\(^4\)\(^8\)\(^9\)

These calciﬁed micronodules increase in size and density and coalesce together to form calciﬁed air space consolidation and ground-glass opacities. This is usually associated with calciﬁed micronodular interlobular septal thickening giving a ‘crazy paving’ appearance.\(^8\)

Crazy paving can be seen in many other conditions, including pulmonary infection, pulmonary hemorrhage, ARDS, and alveolar proteinases. In PAM, interlobular septal thickening is usually of calciﬁc density. Other typical ﬁndings are apical bullae and bilateral pleural cyst. These apical bullae can be seen on chest radiograph and HRCT.\(^2\)

Although the diagnosis of PAM can be established radiologically, bronchoalveolar lavage or lung biopsy might be required to conﬁrm the diagnosis by demonstrating microliths that are typically periodic acid-Schiff positive and composed of centric calcareous lamellae around a central nucleus.\(^3\)\(^4\)\(^8\)\(^9\)\(^10\)

Our patient had a bronchoalveolar lavage, which showed cellular smears composed of scattered lamellar microliths accompanied by many foamy macrophages and some bronchial epithelial cells. Genotyping for SLC34A2 gene mutations can be useful for screening family members, with appropriate genetic counseling. However, it is not currently clinically informative or necessary for diagnosis.\(^1\)\(^3\)\(^4\)\(^8\)

Since the SLC34A2 gene is expressed by extrapulmonary tissue such as kidneys, prostate, testicles, seminal vesicles, pancreas, and liver, patients with PAM can have extrapulmonary calcification such as medullary nephrocalcinosis, nephrolithiasis, and calcification of the seminal vesicles.\(^3\)\(^4\)\(^7\)

Azoospermia due to epididymal and periurethral calcification has been reported.\(^11\) Our patient did not have extrapulmonary ﬁndings.

Currently, there is no effective treatment for PAM. Corticosteroid, calcium chelating agent, and bronchoalveolar lavage have been used to treat and to slow the progression, and none are reported to be effective. Lung transplant remains the only effective treatment for PAM with no reported recurrence following transplantation.\(^3\)\(^8\)\(^10\)

**CONCLUSION**

PAM is uncommon heredity disorder, which needs a high index of suspicion. Awareness of typical radiological and pathological ﬁndings of PAM will help clinicians, radiologists, and pathologists to make the correct diagnosis.
