Abstract

More than 40 single nucleotide polymorphisms (SNPs) for breast cancer susceptibility were identified by genome-wide association studies (GWASs). However, additional SNPs likely contribute to breast cancer susceptibility and overall genetic risk, prompting this investigation for additional variants. Six putative breast cancer susceptibility SNPs identified in a two-stage GWAS that we reported earlier were replicated in a follow-up stage 3 study using an independent set of breast cancer cases and controls from Canada, with an overall cumulative sample size of 7,219 subjects across all three stages. The study design also encompassed the 11 variants from GWASs previously reported by various consortia between the years 2007–2009 to (i) enable comparisons of effect sizes, and (ii) identify putative prognostic variants across studies. All SNP associations reported with breast cancer were also adjusted for body mass index (BMI). We report a strong association with 4q31.22-rs1429142 (combined per allele odds ratio and 95% confidence interval = 1.28 [1.17–1.41] and \( \rho \) combined = 1.5 \times 10^{-7}), when adjusted for BMI. Ten of the 11 breast cancer susceptibility loci reported by consortia also showed associations in our predominantly Caucasian study population, and the associations were independent of BMI; four FGFR2 SNPs and TNRC9-rs3803662 were among the most notable associations. Since the original report by Garcia-Closas et al. 2008, this is the second study to confirm the association of 8q24.21-rs13281615 with breast cancer outcomes.

Introduction

Breast cancer is the most common cancer in women in the developed world, with 22,700 new cases and 5,100 deaths anticipated in Canada for 2012 [1]. While environmental and lifestyle risk factors contribute to most of the variation in breast cancer risk, twin studies have shown substantial contribution of inherited genetic risk factors to disease susceptibility [2,3]. Linkage and family-based studies have identified high and moderate penetrance mutations in genes such as BRCA1 [4], BRCA2 [5], PTEN [6], ATM [7], TP53 [8], BRIPL [9], PALB2 [10] and CHEK2 [11] contributing to hereditary breast cancer; however, these mutations occur rarely in the general population. Further, linkage studies failed to identify additional genes/mutations associated with high or moderate risk of breast cancer. Therefore, it has been hypothesized that most of the genetic risk of breast cancer, for both familial and sporadic cases in the general population, may involve a combination of multiple low penetrance genes/loci, each contributing to an overall genetic risk of breast cancer [12].

Over the past five years, several genome-wide association studies (GWASs) reported breast cancer susceptibility variants (i.e., single nucleotide polymorphisms, SNPs) at multiple loci [13–22]. A large-scale candidate gene study also identified an additional locus (caspase 8 coding SNP, rs1045485) associated with breast cancer risk [23]. The low penetrance common SNPs identified to date explain less than 10% of the genetic risk of breast cancer [22]. Taken together, pathogenic germline mutations and low penetrance variants identified thus far only account for a small fraction of the genetic risk of breast cancer, suggesting that additional variants remain to be identified [24].

Recently, we conducted a two-stage GWAS using sporadic breast cancer cases and apparently healthy controls and identified six SNPs (located at chromosomes 4, 5, 16 and 19) that appeared to be associated with breast cancer susceptibility [21]. In a combined sample size of 1,455 breast cancer cases and 1,536 healthy controls from two independent stages, these SNPs showed modest risk of breast cancer (observed odds ratios (ORs) range: 1.22–1.45).
It is an internationally accepted practice to replicate GWAS findings in multiple independent studies with cases and controls of both similar and diverse ethnic backgrounds to assess the robustness and generalizability of the identified associations, respectively. Therefore, in the current study, we further investigated the six putative breast cancer susceptibility SNPs that we have reported previously [21] by conducting an independent replication study (stage 3), using breast cancer cases and controls. The study subjects were predominantly of Caucasian ancestry drawn from the same geographical region in Canada as in our previous study. Further, we evaluated the GWAS variants for breast cancer susceptibility reported by various consortia. These include the Breast Cancer Association Consortium [13,18], the Effectiveness of Additional Reductions in Cholesterol and Homocysteine Collaborative Group [13], the Nurses’ Health Study [14], the National Cancer Institute Cancer Marker of Susceptibility Project [14] and the National Heart, Lung, and Blood Institute Framingham Heart Study [15]. We compared the consortia reported variants with our study population to explore the extent of conformity to previous findings within the Caucasian populations, and for the strengths of associations for the sample size utilized in this study. Since obesity is a well-established risk factor for post-menopausal breast cancer [25] and is a heritable trait [26], we also adjusted the identified variant-breast cancer associations for body mass index (BMI) to examine whether the variants are associated with breast cancer risk, through BMI or through different pathways. We assessed variability in disease susceptibility by clinicopathological characteristics such as menopausal status, family history of breast cancer, luminal A status of tumors, tumor grade and tumor stage. Finally, we explored the associations of the six putative susceptibility SNPs identified in our earlier study and the previously published consortia SNPs with breast cancer outcomes.

Materials and Methods

Study participants

All breast cancer cases (n = 2,750) used in this study had a confirmed diagnosis of breast cancer in the province of Alberta, Canada, and participated in provincial tumor bank projects in operation since 2001 (the PolymX Project, 2001–2005 and subsequently merged with the Canadian Breast Cancer Foundation (CБСF) Tumor Bank, 2005 to present; http://www.abtumorbank.com/), Alberta, Canada) [21,27]. The tumor bank accredits tumor tissues and blood samples from patients with confirmed diagnoses of breast and other cancer types, through hospitals (publicly funded comprehensive cancer care centres managed by the Alberta Health Services (AHS)) in Edmonton and Calgary in the province of Alberta, Canada. The tumor bank database contains well-annotated clinicopathological information for the banked specimens. The CBCF Tumor Bank currently holds blood from more than 8,000 individuals from various cancer types, as a source of germline DNA for genotyping, in addition to tumor tissue specimens. Apparently-healthy (i.e., confirmed not to have had a diagnosis of any cancer) controls (n = 4,472) were obtained from the Tomorrow Project (http://in-homorrow.ca) and were frequency matched to cases based on ten-year age group. The Tomorrow Project is a large prospective cohort study that started in 2000 and successfully recruited approximately 42,000 Albertans (64% women) by 2012 using a combination of random digit dialling (RDD), and random mail-outs, augmented by email campaigns and social media. Inclusion criteria for initial recruitment to the Tomorrow Project were as follows: (i) aged 35–69 years; (ii) no personal history of cancer, other than non-melanoma skin cancer; (iii) able to complete written questionnaires in English and (iv) currently living in Alberta. Upon enrolment to the Tomorrow Project, participants completed a health and lifestyle questionnaire (including family history of major diseases).

The participants gave written consent to be contacted in the future to provide a blood sample for banking to support research in cancer or chronic diseases, receive invitations to provide updated health and lifestyle information or additional samples in the future, and to linkage with administrative health data to understand patterns of health services utilization and disease occurrence [28]. Absence of prior history of cancer upon study enrolment was confirmed by performing linkage with the Alberta Cancer Registry (http://www.albertahelathservices.ca/poph/hl-poph-surv-cancer-altain-cancer-registry-2009.pdf). As of late 2012, approximately 19,000 Tomorrow Project participants from across Alberta had given a 50 ml non-fasting venous blood sample for banking in multiple aliquots of buffy coat, serum, plasma and red blood cells. Breast cancer cases in this study were of predominantly Caucasian ancestry, and resided in the Edmonton and Calgary regions (sites of tertiary cancer centres in Alberta). The population in these regions accounts for two thirds of the total population of the province of Alberta. Thus, in addition to age matching, the controls were selected from the Tomorrow Project using the same ethnicity and geographic location criteria. Even though socio-economic status (SES) plays a role in health outcomes, differences between SES of cases and controls used in this study and underlying assumptions needs to be validated independently. However, given the universal access to health care as a model adopted in Canada, the influence of SES was therefore considered as minimal, if any. A brief description of demographic characteristics of breast cancer cases and controls is presented in Table 1. Written informed consent to use banked samples to support research was obtained from all the study participants, and the study was approved by the Alberta Cancer Research Ethics Committee, Alberta, Canada.

SNPs and samples used

In this replication study (stage 3), we investigated associations of the six putative breast cancer susceptibility SNPs (4q13.22-rs1429142, 5p15.2-rs1092913, 16q23.2-rs1981867, ZNF577-rs10411161, ZNF577-rs1981867 and ZNF577-rs1878583) [21], that we reported in our previous two-stage GWAS. Stage 3 (total n = 4,228) of the study used an independent set of breast cancer cases (n = 1,294) and healthy controls (n = 2,934). In the combined analyses of all three stages, a cumulative sample size (total n = 7,219) was used. We also assessed the strengths of 11 breast cancer susceptibility SNPs that had been reported by consortia until 2009 (SLCA7-rs4973768 [18], 5p12-rs415084 [16], 5p12-rs10941679 [16], 5q11.2-rs839512 [13], 8q24.21-rs13281615 [13], FGFR2-rs2981579 [19], FGFR2-rs1219648 [14], FGFR2-rs2420946 [14], FGFR2-rs2981582 [13], TNRC9-rs3003662 [13] and COL1A1-rs2075555 [13]). A cumulative sample size of 2,672 breast cancer cases and 4,470 apparently healthy controls were genotyped for these 11 consortia SNPs. Genotype data are available upon request.

SNPs genotyping and quality control

Germline DNA was extracted from peripheral blood samples of both cases and controls using commercially available Qiagen (Mississauga, ON, Canada) DNA isolation kits. All genotyping assays were performed on the Sequenom iPLEX Gold platform (San Diego, CA, USA) using services from the McGill University and Genome Quebec Innovation Center, Montreal, Canada. Within-stage (stage 3 for the six SNPs from our previous GWAS
Table 1. Distribution of age and BMI of breast cancer cases and controls used in the study.

| Characteristics | Breast cancer cases (n = 2750) | Apparently healthy controls (n = 4472) |
|-----------------|---------------------------------|--------------------------------------|
| Median age in years at diagnosis/blood draw [range] | 54 [22–92] | 54 [35–78] |
| <40 | 192 | 343 |
| 40–50 | 710 | 1282 |
| 50–60 | 889 | 1538 |
| 60–70 | 635 | 1144 |
| 70–80 | 242 | 162 |
| >80 | 64 | 0 |

and a single stage for the 11 consortia SNPs genotype concordance was assessed with 66 duplicate samples (8 cases and 58 controls). Cross platform (Affymetrix vs. Sequenom i.e., stage 1 vs. stage 3 for the six SNPs) was assessed with 17 duplicate samples (5 cases and 12 controls). Between-stage (stage 2 vs. stage 3 for the six SNPs) genotype concordance was assessed with 632 cases and 452 controls. Duplicate samples used for assessing genotype concordances among various stages were randomly selected. Very stringent criteria of SNP call rate >99% was considered to minimize false positive associations due to missing genotype counts and HWE criteria of P<10^{-6} in control subjects were adopted.

Association analyses and statistical considerations

Overall analyses. Allelic associations of SNPs with breast cancer susceptibility were evaluated with correlation/trend tests with one degree of freedom (d.f.). The strengths of allelic and genotypic associations were estimated using unconditional logistic regressions and reported as ORs and 95% confidence intervals (CIs). To increase sample size and hence the statistical power to detect associations that were larger than genotypic relative risk of 1.2. Whenever multiple SNPs were tested, correction for multiple hypotheses testing was performed by P=0.05/number of tests. We considered all SNPs from our stage 1 GWAS (782,838 SNPs) to calculate genome-wide significance (P<5x10^{-8}) for the six replicated SNPs. Correlation/trend tests were carried out using SNP and Variation Suite v7.6.11 (Golden Helix, Inc., Bozeman, MT, www.goldenhelix.com) [31]. The observed and adjusted allelic and genotypic ORs and 95% CIs and adjusted P values were estimated using logistic models in PLINK (http://pngu.mgh.harvard.edu/~purcell/plink/) [32]. All the general statistical analyses were conducted using R 2.15.1.

Results

Genotyping assays of the 17 SNPs considered in this study were successful with a SNP call rate of >99%. Average within-stage genotype concordance was 100% while cross-platform genotype concordance was >99%; between-stage average genotype concordance was also 100%. We reasoned that negligible percentage (<1%) of discordance was unlikely to influence SNPs.

*Note: MAF = Minor Allele Frequency, OR = Odds Ratio, CI = Confidence Interval.*
breast cancer associations and hence all the genotype data were considered for the downstream association analyses. The genotype distributions from the six SNPs (our previous work) showed conformity with Hardy-Weinberg Equilibrium (HWE) criteria in control subjects. Similarly, the genotype distributions from the 11 consortia SNPs were also in agreement with HWE. Minor allele frequencies (MAFs) of the six SNPs across all stages and the 11 consortia SNPs were comparable with the published MAFs, reflecting the robustness of the genotyping platform vis-a-vis negligible genotyping errors (Tables 2 and S1) and confidence in the reported associations.

### Association of previously identified (consortia SNPs) breast cancer susceptibility loci

Except for COL1A1-rs2075555, we successfully replicated the association of ten consortia reported breast cancer susceptibility loci in our study population at \( P < 0.05 \) (Table S1). These SNPs remained statistically significant after correction for multiple hypothesis testing \( (P < 0.05/11 = 0.004) \). Four FGFR2 SNPs and TNRC9-rs3803662 showed the strongest associations attaining the commonly adopted genome-wide significance level \( (P < 5.0 \times 10^{-8}) \), with similar ORs to the original study findings \([13,14,19]\). After adjusting for BMI, five SNPs remained statistically significant \((P < 4.2 \times 10^{-7}) \) (Table S1). The adjusted per allele ORs and 95% CIs were also similar to the observed ORs and 95% CI (Table S1), indicating that these SNP-breast cancer associations are independent of the pathway linking BMI and risk of breast cancer.

### Replication of the six putative SNPs in stage 3 analyses

Of the six putative breast cancer susceptibility SNPs that we reported earlier, 4q31.22-rs1429142 showed consistent reproducibility across all three stages. The variant at 5p15.2-rs1092913 also retained statistical significance for increased breast cancer risk in the current independent replication stage 3 study at \( P < 0.05 \) (Table 2), and remained statistically significant after correction for multiple hypothesis testing \( (P < 0.05/6 = 0.006) \). The magnitude and direction of per allele ORs and 95% CIs of both SNPs were consistent with our previous findings \([21]\) while slightly elevated ORs and 95% CIs were observed for heterozygotes and variant homozygotes (Table 2), conforming to the additive model of genetic inheritance. After adjustment for BMI, both 4q31.22-rs1429142 and 5p15.2-rs1092913 remained statistically significant at \( P < 0.05 \), while both adjusted per allele and genotypic ORs and 95% CIs of 4q31.22-rs1429142 were larger than the observed ORs. The remaining four SNPs did not show statistical significance at \( P < 0.05 \) in this stage 3 study.

### Combined analyses of the six putative SNPs (stages 1+2+3)

In the combined analyses (stages 1+2+3), five of the six SNPs were significantly associated with increased breast cancer risk at \( P < 0.05 \), the exception being 16q23.2-rs1981867 which showed marginal statistical significance \( (P = 0.06) \) (Table 2). Again, 4q31.22-rs1429142 and 5p15.2-rs1092913 showed the strongest associations after multiple hypothesis correction. The five SNPs retained statistical significance after adjusting for BMI. Interestingly, 4q31.22-rs1429142 achieved near genome-wide significance level with greater per allele and genotypic ORs and 95% CIs (adjusted \( P = 1.5 \times 10^{-7} \)), adjusted per allele OR and 95% CI = 1.28 \([1.17–1.41]\), adjusted ORheterozygote and 95% CI = 1.32 \([1.17–1.48]\) and adjusted ORhomozygote and 95% CI = 1.52 \([1.16–2.00]\), indicating that the 4q31.22-rs1429142-

MA, minor allele; $P_{het}$, $P$ for heterogeneity.

Common controls used for conducting each of the subgroup analyses mentioned above.

*Adjusted for BMI.
breast cancer association may be linked to the BMI pathway of breast cancer risk elevation (Table 2). **p** = 2.0 × 10⁻⁶, adjusted per allele OR and 95% CI = 1.21 [1.10–1.34], adjusted ORhet and 95% = 1.20 [1.05–1.36] and adjusted ORhet and 95% CI = 1.53 [1.13–2.06].

**Subgroup analyses**

The previously reported GWAS variants (consortia SNPs), except **COL11A1**-rs2073553, remained statistically significant in subgroups with both pre and postmenopausal women, luminal A cases, cases with or without family history of breast cancer, low tumor grade and operable tumor stage at adjusted **p**< 0.05 (Table S2). The adjusted per allele ORs, 95% CIs and **p** values were also comparable to the overall analyses, with similar magnitudes and directions of risk (Tables S1 and S2). Of these, the four **FGFR2** SNPs retained genome-wide significance level in subgroups with luminal A cases, cases with family history of breast cancer, low tumor grade and operable tumor stage while 8q24.21-rs13281615 and **TNRC9**-rs3803662 showed genome-wide significance level associations only in cases with low tumor grade and operable tumor stage, respectively. **SLCA7**-rs4973768, 5q11.2-rs889312, 8q24.21-rs13281615 and **TNRC9**-rs3803662 showed marginal associations in subgroup with non-luminal A cases. Similarly, 5q11.2-rs889312 and **TNRC9**-rs3803662 showed significant associations in cases with high tumor grade. None of the SNPs showed significant associations in cases with non-operable tumor stage, with the possible exception of 5q11.2-rs889312 which showed a marginally statistically significant association (adjusted **p** = 0.04).

The associations of the six GWAS-identified putative breast cancer susceptibility SNPs (Table 2) based on tumor grade and stage.

**Association of SNPs with breast cancer outcomes**

Of the 17 SNPs tested for their associations with breast cancer outcomes, 8q24.21-rs13281615 was significantly associated with reduced risk of both RFS (adjusted **p** = 0.001 and adjusted per allele HR and 95% CI = 0.77 [0.65–0.90]) and OS (adjusted **p** = 0.003, adjusted per allele HR and 95% CI = 0.76 [0.64–0.91]) (Table S3). The remaining 16 SNPs did not show statistically significant associations with breast cancer outcomes at adjusted **p**< 0.05.

**Discussion**

In this independent replication study in Canadian women involving 2,750 breast cancer cases and 4,472 healthy controls, we successfully reproduced the associations of ten previously GWAS-identified breast cancer susceptibility loci, indicating the robustness of the consortia identified SNPs with breast cancer. In
addition, two of the six putative breast cancer susceptibility SNPs (4q31.22-rs1429142 and 5p15.2-rs1092913) from our previous two-stage GWAS also showed robust associations in an independent set of breast cancer cases and healthy controls (stage 3). After adjusting for BMI, 4q31.22-rs1429142 attained near genome-wide significance level (adjusted $P = 1.5 \times 10^{-7}$) (Table 2). A major strength of this study is the consideration of BMI, which allowed confirmation that the genetic contributions to breast cancer are

![Image](https://example.com/image.png)

Figure 1. Regional association plot (top panel) for 4q31.22-rs1429142 using LocusZoom [48], with the association $P$-values ($-\log_{10} P$) on the y-axis and the chromosomal position (hg18) on x-axis. The association of 4q31.22-rs1429142 in stage 1 is shown in purple circle while association in combined stages (1+2+3) after adjusting for BMI is shown in purple diamond. Pair-wise linkage disequilibrium (LD) of 4q31.22-rs1429142 with adjacent SNPs are measured by $r^2$ values (from HapMap Phase II CEU data) and represented by the color of each circle. Neighbouring Refseq genes are shown below the plot. LD profiles (bottom panel) among SNPs located within 100 kb up and downstream of the 4q31.22-rs1429142, using HapMap Phase II CEU data are presented.

doi:10.1371/journal.pone.0062550.g001
independent of one of the major risk factors for breast cancer. An additional strength was our evaluation of the SNP-breast cancer associations as potential prognostic factors for RFS and OS after diagnosis and their relationships with breast cancer clinical and molecular subtypes.

The most notable associations among the ten previously GWAS-identified breast cancer susceptibility loci replicated in this study were with four FGFR2 SNPs (rs2981579, rs1219648, rs2420946 and rs2901582) and TNRC9-rs3063662 (observed \(P=7.0 \times 10^{-10}\) and adjusted \(P<4.2 \times 10^{-8}\) [Table S1]). The magnitude and direction of the associations were similar to those reported in the original GWASs (observed per allele OR ranges: 1.17–1.26) [13–16,18,19], suggesting the robustness of these associations with breast cancer susceptibility. Further, results from the subgroup analyses were consistent with the previous reports [33–35], supporting the hypothesis that FGFR2 loci (rs1219648, rs2420946 and rs2901582) are associated with increased risk of breast cancer, especially in familial breast cancer cases (\(P_{het}<0.02\)), and associated with the better prognosis luminal A type or estrogen receptor positive breast cancers (\(P_{het}<0.001\) [Table S2] [33–35]).

Of the six putative breast cancer susceptibility SNPs reported in our previous two-stage GWAS, our independent stage 3 analyses successfully replicated the associations of 4q31.22-rs1429142 and 5p15.2-rs1092913 with increased risk of breast cancer. In the combined analyses, five of the six reported associations from our previous GWAS retained statistical significance, the exception being 16q23.2-rs1981867. These five SNPs should be further tested independently in additional cases and controls to assess their being 16q23.2-rs1981867. These five SNPs should be further successfully replicated the associations of 4q31.22-rs1429142 and our previous two-stage GWAS, our independent stage 3 analyses 4q31.22-rs1429142, there was a substantial increase from the previous GWAS retained statistical significance, the exception being 16q23.2-rs1981867. These five SNPs should be further tested independently in additional cases and controls to assess their role in breast cancer etiology. When adjusted for BMI, we observed near genome-wide significant association for 4q31.22-rs1429142 (adjusted \(P=1.7 \times 10^{-7}\)) while 5p15.2-rs1092913 remained statistically significant (adjusted \(P=1.9 \times 10^{-4}\)). For 4q31.22-rs1429142, there was a substantial increase from the observed ORs (per allele = 1.22, OR_{homozygote} = 1.26 and OR_{heterozygote} = 1.36) to adjusted ORs (per allele = 1.29, OR_{homozygote} = 1.32 and OR_{heterozygote} = 1.52). These results indicate that the 4q31.22-rs1429142-breast cancer association may be linked to the BMI pathway of breast cancer risk elevation. This observation is in contrast to the ten GWAS-identified consortia reported SNP-breast cancer associations, and hence requires replication in independent set of breast cancer cases and controls, probably through collaborative efforts involving large international consortia. Both 4q31.22-rs1429142 and 5p15.2-rs1092913 showed statistically significant associations with breast cancer in subgroups with pre and postmenopausal women, cases with luminal and non-luminal A tumors, with and without family history of breast cancer, low and high tumor grade and operable tumor stage at diagnosis. The SNP 5p15.2-rs1092913 is also located in a gene desert, with the closest gene EDNRA 112 kb downstream of the SNP. The EDNRA gene encoded protein is a cell surface bound receptor involved in various fundamental cellular processes by interacting with endothelins (widely expressed cytokines in various tissues) [36]. SNPs in or near the EDNRA gene have been associated with intracranial aneurysm risk [37], hypertension [38] and migraines [39]. This SNP is ~112 kb away from the EDNRA gene locus and we therefore queried the SCAN database [40], which uses HapMap human lymphoblastoid cell lines to identify putative expression quantitative trait loci. We found that 4q31.22-rs1429142 is associated with differential expression of five other genes (quantitative transmission disequilibrium test \(P<0.0001\), implemented in the SCAN database) involved in at least one type of cancer – i.e., kinesin family member 3B (KIF3B) [41], paxillin (PWX) [42], general transcription factor II A, 12 kDa (GTF2A2) [43], PTPRE interacting protein, binding protein (liprin beta 2) (PTPFRIP2) [44] and tumor protein p63 regulated 1-like (TPRG1L) [45]. However, the allele of 4q31.22-rs1429142 responsible for these is unknown and future fine mapping studies to identify the causal variant and to investigate its allele specific effects are warranted.

In summary, our study not only provided supportive evidence for the robustness of the breast cancer susceptibility SNPs previously identified by consortia, but also identified a new locus at 4q31.22-rs1429142 for contributing to breast cancer susceptibility, lending credence to the continued research efforts in search of common variants for breast cancer.
