(Dated: July 22, 2020)

Ultrathin ferromagnets with frustrated exchange and the Dzyaloshinskii-Moriya interaction can support topological solitons such as skyrmions and antiskyrmions, which are metastable and can be considered as particle-antiparticle counterparts. When spin-orbit torques are applied, the motion of an isolated antiskyrmion driven beyond its Walker limit can generate skyrmion-antiskyrmion pairs. Here, we use atomistic spin dynamics simulations to shed light on the scattering processes involved in this pair generation. Under certain conditions a proliferation of these particles and antiparticles can appear with a growth rate and production asymmetry that depend on the strength of the chiral interactions and the dissipative component of the spin-orbit torques. These features are largely determined by scattering processes between antiskyrmions, which can be elastic, result in bound states, or annihilate.

Condensed matter offers a fascinating test bed to explore different concepts in non-relativistic and relativistic quantum field theories [1], with some prominent examples being massless Dirac quasiparticles in graphene [2], Majorana fermions in superconductors [3–5], and anyons in two-dimensional electron gases [6]. In ultrathin ferromagnets, chiral interactions of the Dzyaloshinskii-Moriya form [7–12] allow for the existence of skyrmions [13, 14], which are topological soliton solutions to a nonlinear field theory bearing resemblance to a model for mesons and baryons proposed by Skyrme [15, 16]. While these two-dimensional particles have been actively studied for their potential in information storage applications [17, 18], their original ties to nucleons have been revisited through three-dimensional extensions called hopfions [19], which also provide an intriguing connection to Lord Kelvin’s proposal for a vortex theory of atoms [20].

Pairs of skyrmions and antiskyrmions, their antiparticle counterpart, can be generated in a variety of ways, such as nucleation under local heating [21], homogenous spin currents [22, 23], and surface acoustic waves [24]. Pairs also appear in ultrathin chiral ferromagnets with frustrated exchange interactions when the magnetization dynamics is driven by spin-orbit torques (SOT) [25]. While both skyrmions and antiskyrmions are metastable states in such systems [26–28], their motion can be qualitatively different under spin orbit torques [25]. In particular, an antiskyrmion driven beyond its Walker limit can shed skyrmion-antiskyrmion pairs, much like the vortex-antivortex pairs produced during vortex core reversal [29], which are then driven apart by the SOT. Because such nonlinear processes are observed to involve a variety of creation and annihilation events involving particles and antiparticles, the intriguing analogies with high energy physics compels us to explore whether this system could offer any insight, albeit tangential, into the more general question of matter-antimatter asymmetry in the universe. After all, the Sakharov conditions for baryogenesis [30], namely baryon number violation, charge conjugation (C) and combined charge conjugation-parity (CP) violation, and out-of-equilibrium interactions, appear to be naturally fulfilled in the aforementioned case: no conservation laws exist for the number of skyrmions and antiskyrmions, the Dzyaloshinskii-Moriya interaction (DMI) breaks chiral symmetry and lifts the degeneracy between skyrmion and antiskyrmions, and dissipative torques (spin-orbit and Gilbert damping) representing nonequilibrium processes play a crucial role in pair generation. In this Letter, we examine theoretically the microscopic processes leading to an imbalance in the number of skyrmions and antiskyrmions produced as the result of SOT-driven antiskyrmion dynamics.

The system studied is illustrated in Fig. 1(a). Following Refs. 25 and 31 we consider a ferromagnetic PdFe bilayer, which host the skyrmions (s) and antiskyrmions (s̄), on an Ir(111) substrate through which we assume an electric current flows in the film plane, resulting in a spin current generated by the spin Hall effect flowing in the z direction and polarized along p, which is characterized by the angle θp measured from the x-axis. A magnetic field B is applied along the z direction which defines the uniform background state of the PdFe system. We model the magnetic properties of the PdFe film with a hexagonal lattice of magnetic moments m, one atomic layer in thickness, whose dynamics is solved by time-integration of the Landau-Lifshitz equation with Gilbert damping and spin-orbit torques,

\[
\frac{d\mathbf{m}}{dt} = \frac{1}{\hbar} \mathbf{m} \times \mathbf{B}_{\text{eff}} + \alpha \mathbf{m} \times \frac{d\mathbf{m}}{dt} + \mathbf{m} \times \frac{1}{\mu} \frac{\partial H}{\partial \mathbf{m}}
\]
The linear, deflected, and trochoidal regimes denote the motion involving single-particle dynamics, while annihilation represents the region in which the seed loses its metastability. The focus here is on $ss$ pair generation that predominantly occurs under small fieldlike torques and large dampinglike torques. We simulated the dynamics in a variety of system sizes $L \times L$ with periodic boundary conditions, with $L$ ranging from 100 to 800 in order to mitigate finite size effects that primarily involve collisions from generated particles re-entering the simulation area. The time integration of Eq. (1) was performed using the Heun method with a time step of 1 fs.

The propensity for the initial seed $s$ to produce particles ($s$) and antiparticles ($\bar{s}$) is determined by the scattering processes that immediately follow the formation of the $ss$ pair, which depend on the strengths of $\beta_{FL}$ and $\beta_{DL}$. Three key scattering processes are illustrated in Fig. 2 for $\theta_p = 0$. The different processes illustrated typically occur for specific ranges of field-like and damping-like (DL) spin-orbit torques [25].
like parameters as will be discussed later. We use a color map based on the local topological (skyrmion) charge density $q$, which is computed from three neighboring moments $\mathbf{m}_i, \mathbf{m}_j, \mathbf{m}_k$ as [33]

$$q_{ijk} = -\frac{1}{2\pi} \tan^{-1} \left[ \frac{\mathbf{m}_i \cdot (\mathbf{m}_j \times \mathbf{m}_k)}{1 + \mathbf{m}_i \cdot \mathbf{m}_j + \mathbf{m}_j \cdot \mathbf{m}_k + \mathbf{m}_k \cdot \mathbf{m}_i} \right].$$

(3)

This represents the contribution from half a unit cell. We use $Q$ to denote the total charge, which represents a sum over the $q_{ijk}$, and we adopt the convention where $Q = 1$ for $s$ and $Q = -1$ for $\bar{s}$. The processes are characterized by their potential for particle production, measured by $N = N_s + N_{\bar{s}}$, which denotes the total number of skyrmions ($N_s$) and antiskyrmions ($N_{\bar{s}}$) produced from the initial antiskyrmion, and by the asymmetry in this production, which is measured by the parameter $\eta = (N_s - N_{\bar{s}})/N$. We consider only processes for which $N > 0$ (the seed $s$ is not included in this count). In Fig. 2(a) a maximal production ($N = 2$), minimal asymmetry ($\eta = 0$) scattering process leading to the proliferation of particles is shown for $(\hbar\beta_{FL}, \hbar\beta_{DL}) = (0.02, 1.5)$ meV. An $ss$ pair nucleates from the tail of the $s$ seed as it undergoes trochoidal motion, which then splits and is followed by a number-conserving collision between the two $s$ particles. The $s$ escapes the zone of nucleation and the two $s$ particles become new sources of $ss$ pair generation. In this scenario, $s$ and $\bar{s}$ are produced in equal numbers and the process continues indefinitely but can be slowed by annihilation processes, which become more probable as the density of particles increases. In Fig. 2(b), a similar $N = 2, \eta = 0$ process is shown for $(\hbar\beta_{FL}, \hbar\beta_{DL}) = (0.1, 1.35)$ meV, but here the scattering between the two $s$ results in a transient higher-order $Q = -2$ antiskyrmion state ($2\bar{s}$), which subsequently decays into an $ss$ bound pair that executes a rotational motion about its centre of mass. As a result, further pair generation is suppressed. Fig. 2(c) illustrates a minimal production ($N = 1$), maximal asymmetry ($\eta = 1$) process at $(\hbar\beta_{FL}, \hbar\beta_{DL}) = (0.13, 1.1)$ meV, where the scattering between the seed and generated $s$ results in a non-conservation process where the seed $s$ is annihilated, which takes place via the creation and annihilation of a meron-antimeron [34]. This scattering event leaves the generated $s$ to propagate away and the surviving $\bar{s}$ to restart the process.

Examples of the growth rates are given in Fig. 3, where $Q(t)$ is shown for the three cases presented in Fig. 2. The data are obtained from simulations of a $500 \times 500$ system over 0.1 ns with $\theta_p = 0$. Above this timescale, propagating particles can re-enter the simulation geometry through the periodic boundary conditions which result in spurious collisions and annihilation events. $Q_s$ and $Q_{\bar{s}}$ are found by summing over separately the contributions from $q_{ijk} > 0$ and $q_{ijk} < 0$, respectively. Fig. 3(a) illustrates the growth where the process in Fig. 2(a) dominates, where a proliferation of particles can be seen. Unlike the single event in Fig. 2(a) the growth in Fig. 3(a) also comprises processes such as those described in Figs. 2(b) and 2(c), which results in an overall asymmetry in the production and finite topological charge that increases with time. When the seed immediately undergoes the scattering process in Fig. 2(b), the generation stops for all future times and a stasis regime is found [Fig. 3(b)]. Such processes can also occur after a certain time interval following proliferation, which results in premature saturation. Cases in which the scattering process in Fig. 2(c) repeats periodically results in an approximately linear growth in the number of skyrmions, which is shown in Fig. 3(c).

A $(\beta_{FL}, \beta_{DL})$ phase diagram of the skyrmion production and asymmetry is presented in Fig. 4(a). As for Fig. 3, the data were obtained after simulating 0.1 ns on a $500 \times 500$ spin system with periodic boundary conditions and $\theta_p = 0$. The size of the circles represents $N$ on a logarithmic scale, while the color code represents $\eta$ on a linear scale. Three different regimes can be identified visually as the strength of $\beta_{FL}$ is increased. For low values of $\beta_{FL}$ (primarily $\hbar\beta_{FL} \lesssim 0.07$ meV), we observe a regime in which proliferation dominates where large numbers of $s$ and $\bar{s}$ are generated, which is mainly driven by the process in Fig. 2(a). Both $N$ and $\eta$ increase with the dampinglike torques in this regime, as shown in Figs. 4(b) and 4(c), respectively, which can understood from the fact that $\beta_{DL}$ represents a nonconservative torque that transfers spin angular momentum into the system. For intermediate values of $\beta_{FL}$ (primarily $0.08 \lesssim \hbar\beta_{FL} \lesssim 0.11$ meV), a linear growth regime is seen which is characterized by $\eta \approx 1$ and moderate values of $N$. As for the proliferation regime, the rate of production in the linear regime increases with $\beta_{DL}$ as shown in Fig. 4(d). Finally, for large values of $\beta_{FL}$ (primarily $\hbar\beta_{FL} \gtrsim 0.13$ meV) and close to boundaries of the generation phase, we observe

![FIG. 3. Representative examples of different growth regimes of the total skyrmion charge. $Q$ for three values of $(\hbar\beta_{FL}, \hbar\beta_{DL})$: (a) Proliferation, $(0.02, 1.5)$ meV. (b) Stasis or premature saturation, $(0.13, 1.1)$ meV. (c) Linear growth, $(0.1, 1.35)$ meV.](image-url)
FIG. 4. (a) \((\beta_{FL}, \beta_{DL})\) phase diagram illustrating the total number of skyrmions and antiskyrmions produced over 0.1 ns, where \(N\) is represented by a circle size on a logarithmic scale, and the asymmetry parameter, \(\eta\), shown on a linear color scale. (b) \(N\) and (c) \(\eta\) as a function of DL torques for the proliferation regime (for different FL torques). (d) \(N\) as a function of DL torques for linear growth \((\eta = 1)\).

predominantly a stasis regime where generation stops after the nucleation of a single \(s\bar{s}\) pair and the formation of a bound \(s\bar{s}\) state, as shown in Fig. 2(b). We note that both stasis and proliferation states can be found at the phase boundaries. This results from the fact that the scattering processes in Figs. 2(b) and 2(c) involve nearly identical energy barriers (in the absence of SOT), where only slight differences in the relative helicities of the scattering \(s\) states determine the outcome. Additional information on the minimum energy paths computed for the merging of antiskyrmions at zero SOT, using the method described in Ref. 35, is given elsewhere [36].

The roles of DMI and the spin polarization angle are shown in Fig. 5, where \((\theta_p, D_{ij})\) phase diagrams for \(N\) and \(\eta\) are presented for the three distinct dynamical regimes discussed above: proliferation \([0.02, 1.5]\), Fig. 5(a)], linear growth \([0.1, 1.35]\, meV, Fig. 5(b)], and stasis \([0.13, 1.1]\, meV, Fig. 5(c)]], where the figures in parenthesis indicate values of \((\hbar\beta_{FL}, \hbar\beta_{DL})\) in units of meV. A weak dependence in the \(\theta_p\) can be seen. This arises from the interplay between the SOT-driven dynamics of the antiskyrmion helicity, which possess a two-fold rotational symmetry about the antiskyrmion core in its rest state, and the underlying hexagonal lattice structure, which introduces a weak lattice potential that arises because of the compact nature of the core [25]. Variations in the magnitude of \(D_{ij}\), on the other hand, lead to greater changes in the qualitative behavior, where transitions between stasis, linear growth, and proliferation can be seen as \(D_{ij}\) is increased for all three base cases considered. This behavior is exemplified in Fig. 5(d) where \(N\) and \(\eta\) are shown as a function of \(D_{ij}\) for the cases shown in Fig. 5(a). These results also suggest that a finite threshold for \(D_{ij}\) is required for pair generation to take place, a threshold that is also dependent on the strength of the SOT applied.

With the frustrated exchange and in the absence of dipolar interactions, setting \(D_{ij}\) to zero restores the chiral symmetry between skyrmions and antiskyrmions, where SOTs result in circular motion with opposite rotational sense for \(s\) and \(\bar{s}\) [25–27, 37]. While the focus here has been on the consequences of generation from an antiskyrmion seed, the choice of an anisotropic form of the Dzyaloshinskii-Moriya interaction, i.e., one that energetically favors antiskyrmions over skyrmions [38–42],
would result in the opposite behavior whereby skyrmion seeds would lead to pair generation and proliferation of antiskyrmions over skyrmions [25]. Ultimately, the asymmetry in the production of particles and antiparticles from a given seed is driven by the strength of the chiral symmetry breaking, here measured by $D_{ij}$, and the nonequilibrium torques leading to pair generation, here characterized by $\beta_{DL}$.

Minimum energy path calculation for antiskyrmion merging and annihilation

The outcome of a $\bar{s}\bar{s}$ scattering event under SOTs may conserve skyrmion number and consist in either a higher order $2\bar{s}$ state, or, through an elastic collision, an unchanged $\bar{s}\bar{s}$ state. Alternatively, the process may be non-conservative and the collision may result in a single $\bar{s}$ state. In order to understand what determines the outcome of a scattering event, we look at minimum energy paths (MEPs) on the multidimensional energy surface defined by the Hamiltonian in Eq. (2) of the main text at zero SOT, i.e., $\beta_{FL} = \beta_{DL} = 0$. The material parameters are that of Pd/Fe/Ir(111), as given in the main text. We use the geodesic nudged elastic band method (GNEB) [35] to compute the MEPs, for which intermediate states of the system along the reaction coordinate are referred to as images.

First, the MEP for the merging into a higher order $2\bar{s}$ state is shown in Fig. 6(a), where the image index is shown in the bottom left-hand corner. The corresponding energy profile along the reaction coordinate is shown in Fig. 6(c). This path resembles the mechanism identified in Fig. 2(b) of the main text, which, under SOTs, subsequently results in the formation of a bound $\bar{s}\bar{s}$ pair and suppresses generation (see Fig. 2h: stasis regime). The initial state in the GNEB method is set as a pair of metastable, isolated $\bar{s}$ states, where both $\bar{s}$ have the same helicity. The antiskyrmions then undergo a rotation of helicity, during which the total energy increases, to reach a higher energy configuration at image 6. The next image, image 7, corresponds to the barrier top, in the form of a saddle point, and precedes the merging. At the saddle point, the antiskyrmions come into contact from the side and join through their counter-clockwise, and clockwise rotating Bloch axes, respectively, with a helicity difference of about $\pi$ rad. The corresponding energy barrier is found to be $\Delta E = 1.089 J_1$, where $J_1 = 14.73$ meV is the exchange constant for the Heisenberg interaction between nearest-neighbors and is employed here as a characteristic energy scale. Subsequent images correspond to the merging into the final metastable $2\bar{s}$ state via the antiskyrmions’ Bloch axes, accompanied by a decrease in the total energy of the system. The total topological charge remains constant throughout this process.

Next, we describe the path corresponding to the merging of the $\bar{s}\bar{s}$ pair into a single $\bar{s}$, via a process that does not conserve the total topological charge. The MEP is shown in Fig. 6(b), with the corresponding energy profile shown in Fig. 6(d). This mechanism resembles the process presented in Fig. 2(c) of the main text, through which an inelastic collision of two antiskyrmions results in the destruction of the seed, and leads to a linear growth in the number of skyrmions [Fig. 3(c)]. Similar to the me-

FIG. 6. (a, b) Minimum energy paths for the merging of the $\bar{s}\bar{s}$ pair into a (a) $2\bar{s}$ state, (b) $\bar{s}$ state. The image indices are given in the bottom left-hand corner. The graphical representation is identical to that used in Fig. 2 of the main text. (c, d) The associated energy profile along the (normalized) reaction coordinate, where (c) corresponds to the paths that results in the $2\bar{s}$ state, and (d) corresponds to the path that results in the $\bar{s}$ state. The total topological charge remains constant at $Q = -2$ in (c), while its variation with the reaction coordinate is shown in (d). The inset in (c) shows the saddle point configuration (image 7), where the dashed arrows indicate the reference axis along which the clockwise (CW) or counter-clockwise (CCW) Bloch states are defined. The inset in (d) represents an expanded view of the region around the energy barrier.

The above results show that, in the generation regime, the initial state is set as a pair of isolated, metastable $\bar{s}$ states, where the $\bar{s}$ have the same helicity. From there, the helicities of the antiskyrmions rotate as the energy increases, until the system reaches the barrier top at image 6. This state is very similar to the saddle point of the MEP in Fig. 6(a), with, once more, a corresponding energy barrier of $\Delta E = 1.089J_1$. However, the difference in the helicities seem to be, in this case, slightly inferior to $\pi$ rad. The following images correspond to the merging into a metastable single $\bar{s}$ state. This involves the destruction of one unit of negative topological charge, which occurs via the nucleation of a meron of charge $Q = +\frac{1}{2}$ at image 8. This is accompanied by a sharp decrease in the total energy of the system, as well as a drop in the total negative topological charge, from $-2$ to $-1$. The meron then annihilates with the extra antimeron of charge $Q = -\frac{1}{2}$, thus leaving a single $\bar{s}$ state of charge $Q = -1$ at image 9, accompanied by a further drop in the total energy.

The above results show that, in the generation regime,
the scattering processes undergone by the $\bar{s}$ seed closely resemble the paths of minimum energy at zero SOT. Additionally, we find that the paths for the merging of the $\bar{s}\bar{s}$ pair into either a $2\bar{s}$ state, or a $\bar{s}$ state, traverse very similar saddle points, where only a small relative difference in the helicities appears to determine the fate of the final state. The associated energy barriers are practically identical and relatively low, of the order of $J_1$. This weak differentiation between the saddle points is in line with the fact that the boundaries of the phase diagram in Fig. 4 are not sharp, and that small variations in the applied torques are sufficient to transition between the stasis and proliferation regimes.
