Increasing attention has been directed toward assessing mutational fallout of stereocilin (STRC), the gene underlying DFNB16. A major challenge is due to a closely linked pseudogene with 99.6% coding sequence identity. In 94 GJB2/GJB6-mutation negative individuals with non-syndromic sensorineural hearing loss (NSHL), we identified two homozygous and six heterozygous deletions, encompassing the STRC region by microarray and/or quantitative polymerase chain reaction (qPCR) analysis. To detect smaller mutations, we developed a Sanger sequencing method for pseudogene exclusion. Three heterozygous deletion carriers exhibited hemizygous mutations predicted as negatively impacting the protein. In 30 NSHL individuals without deletion, we detected one with compound heterozygous and two with heterozygous pathogenic mutations. Of 36 total patients undergoing STRC sequencing, two showed the c.3893A>G variant in conjunction with a heterozygous deletion or mutation and three exhibited the variant in a heterozygous state. Although this variant affects a highly conserved amino acid and is predicted as deleterious, comparable minor allele frequencies (MAFs) (around 10%) in NSHL individuals and controls and homozygous variant carriers without NSHL argue against its pathogenicity. Collectively, six (6%) of 94 NSHL individuals were diagnosed with homozygous or compound heterozygous mutations causing DFNB16 and five (5%) as heterozygous mutation carriers. Besides GJB2/GJB6 (DFNB1), STRC is a major contributor to congenital hearing impairment.

Conflict of interest

The authors have no conflicts of interest to disclose.

Hearing impairment is an extremely heterogeneous disorder affecting approximately 1 of 1000 newborns (1). At present, 42 genes and 69 loci (http://hereditaryhearingloss.org) are implicated in non-syndromic autosomal recessive deafness (locus notation DFNB). In the European population, 20–40% of non-syndromic hearing loss (NSHL) is due to mutations in GJB2 (MIM: 121011) and GJB6 (MIM: 604418), together comprising the DFNB1 locus (2). With few exceptions, autosomal-recessive NSHL has similar manifestations, wherein hearing loss is severe to profound with prelingual onset (3).

An initial candidate gene approach assigned STRC (MIM: 606440) to chromosome 15q15.3 encompassing the DFNB16 locus (4). Stereocilia form crosslinks necessary for longitudinal rigidity and outer hair cell structure, and upon mechanical deflection, stereociliary transduction sensitive channels open for cellular
depolarization (5, 6). Reverse transcriptase polymerase chain reaction (RT PCR) from several mouse tissues showed strong, nearly exclusive expression in the inner ear (4) and upon knockout, these key structures were absent (7).

STRC deletion frequencies of >1% have been calculated in mixed deafness populations (8, 9) and the incidence of STRC hearing loss is an estimated 1 in 16,000 (10). Accumulating evidence suggests that DFNB16 constitutes a significant proportion of the otherwise genetically heterogeneous etiology comprising NSHL. One challenge impeding diagnostic implementation of STRC screening is the presence of a non-processed pseudogene with 98.9% genomic and 99.6% coding sequence identity (9) residing less than 100 kb downstream from STRC in a region encompassing a segmental duplication with four genes, HISPPD2A (MIM: 610979), CATSPER2 (MIM: 607249), STRC, and CKMT1A (MIM: 613415). Apart from CKMT1A, these pseudogenes have mutations rendering them inactive (10). In the case of pSTRC, inactivity is due to a nonsense mutation in exon 20 (4). Homozygous deletions of STRC and CATSPER2 result in deafness infertility syndrome (DIS; MIM: 611102), characterized by deafness in both males and females, and exclusive male infertility, as CATSPER2 is required for sperm motility. Not only is it challenging to generate accurate sequencing data without pseudogene inclusion, it is even more difficult interpreting such data without the usual reliable resources for mutation interpretation, as these databases are ‘polluted’ with pseudogene data as well.

Materials and methods

The study was approved by the Ethics Committee at the Medical Faculty of Würzburg University. Informed written consent was obtained from all participants/parents.

Subjects

Our study cohort consisted of primarily pediatric individuals. Patients 1–94, with NSHL were recruited through the Comprehensive Hearing Center at Würzburg University Hospital. All patients had mild to profound sensorineural hearing loss (SNHL). Although study participants were counselled primarily for NSHL, additional symptoms were found in a limited minority. Patient 95 with syndromic SNHL was recruited through Charité Universitätsmedizin Berlin. Genomic DNA (gDNA) was extracted from whole blood using standard salt extraction methods.

STRC copy number counting

Individuals 1–93 were screened for copy number variations (CNVs) using the Omni1-Quad v1.0 array (Illumina, San Diego, CA) and analyzed using GenomeStudio version 2011.1. CNV calling was performed with QuantiSNP 2.2 (11) and cnvPartition 3.2.0 (Illumina). Syndromic patient 95 was tested by array CGH using the Agilent 4x180K (Agilent Technologies, Santa Clara, CA) platform. Individual 94 was tested for STRC CNVs by quantitative real-time PCR (qPCR), using unique STRC exon 22 primers excluding the pseudogene (Table S1, Supporting Information; exon 22 primers without M13 tags) and the SensiMix SYBR Green Kit (Bioline, Luckenwalde, Germany).

Primer design and Sanger sequencing of STRC

To exclude pseudogene sequences, two long-range (LR) PCR products were generated for subsequent nested PCR. Primers (Table S1) were designed using Primer3 (version 0.4.0) software (12) or obtained from the literature (9). The RefSeq STRC sequence annotation corresponds to NM_153700.2 and Ensembl ENSG00000166763 (hg 18). STRC and pSTRC sequences were aligned in UCSC Genome Browser (http://genome.ucsc.edu). STRC-specific sequences were verified using BLAT. Although confined to few divergent bases up- and downstream from STRC, we targeted these regions for LR-PCR primer design, placing the divergent nucleotides at the terminal 3' end if possible (Fig. S1).

LR-PCR was performed with the Qiagen LongRange PCR Kit (Qiagen, Hilden, Germany) using cycling profiles in Table S2. Amplification products were diluted 1:1000 to reduce pseudogene carryover from gDNA and then used for nested PCR. A sequencing control in intron 18 overlapping with both LR products was included for pseudogene exclusion confirmation. Nested PCRs (Table S2) and sequencing continued after LR-PCR products were verified negative for a three-nucleotide frameshift, indicative of pSTRC sequence.

Bidirectional sequencing, performed with an ABI 3130xl 16-capillary sequencer (Applied Biosystems, Carlsbad, CA), was analyzed using Genesearch (Phenosystems, Lillois Witterzee, Belgium) and CodonCode Aligner (CodonCode, Dedham, MA). SIFT (13) and PolyPhen-2 (14) predicted amino acid substitution and disease causing potential.

Results

Individuals 1–93 were run on Illumina Omni1-Quad microarrays. We identified 2 cases with homozygous deletions, 5 with heterozygous deletions, and 10 with copy-neutral loss of heterozygosity (LOH) (Fig. 1; Table S3). Using the Agilent 4x180K array, we detected an additional homozygous deletion in syndromic patient 95. None of these individuals displayed disease-relevant CNVs elsewhere. The homozygous deletions were verified via PCR in exon 22 and the heterozygous deletions via qPCR. By qPCR, we also detected heterozygous deletions in both parents of the homozygous patients 1 and 95. Individual 94 did not have a microarray performed to simulate a diagnostic setting for NSHL patients where copy number counting is performed by qPCR. This individual showed a heterozygous
STRC as a major contributor to hearing loss

Deletion, yielding a combined six heterozygous deletions (Table S3).

Thirty-six NSHL individuals, including six heterozygous deletion, 10 LOH and 20 cases without deletion or LOH, were selected for subsequent Sanger sequencing. Of the six heterozygous deletion carriers, three (nos. 3, 4, and 6) presented hemizygous pathogenic STRC mutations following pseudogene exclusion, with an additional patient (no. 5) exhibiting a heterozygous deletion in conjunction with a candidate mutation c.3893A>G (Fig. 1; Table 1). Table S4 summarizes PolyPhen-2 and SIFT prediction outcomes. None of the 10 individuals with copy-neutral LOH exhibited a homozygous pathogenic mutation; one (no. 16) had a heterozygous mutation. Of the 20 individuals without microdeletion or LOH, 1 (no. 24) displayed compound heterozygous pathogenic mutations, 1 (no. 25) a pathogenic mutation in conjunction with the homozygous c.3893A>G variant, and 3 (nos. 22, 23, and 26) heterozygous c.3893A>G variants (Table 1). The remaining cases were mutation negative. The minor allele frequency (MAF) of the c.3893A>G variant in our NSHL cohort is 9%. In 100 normally hearing adults, we identified 18 heterozygous and 2 homozygous
variant carriers, corresponding to an MAF of 11%. Orthologous alignments illustrate strong evolutionary conservation in mutated positions, including the recurrent variant c.3893A>G (Fig. S2).

All patients with biallelic mutations underwent clinical evaluation and, with few exceptions, had audiogram(s) available (Fig. 2). Audiological, clinical and family history descriptions are detailed in Table 2. Besides the 7 DFNB16 patients here, 32 additional patients with biallelic STRC mutations (including 13 cases from four families) have been published so far (8–10, 15, 16) (Table S5). Many of these patients have sloping high-frequency audiometric profiles and together show an age of onset spectrum ranging from birth to childhood.

### Discussion

We analyzed a cohort of 94 NSHL and one syndromic patient and determined three homozygous and six heterozygous STRC deletions. Deletions of 30 kb (two cases), 45 kb (four cases) and 82 kb (two cases) are recurrent (Fig. 1; Table S3), suggesting non-homologous recombination events (17) between highly similar short DNA elements in chromosome 15q15.3. The homozygous STRC deletions described here extend into CATSPER2 and are responsible for male DIS, contributing to the limited cases in the literature (Table S5). Two of the three homozygous deletion patients are pre-pubertal boys unevaluated for fertility. One of them (no. 95) displayed congenital abnormalities and comorbidities (Table 2), which are probably independent of DFNB16. Three of the six heterozygous deletion patients exhibited hemizygous pathogenic mutations in the second allele, consistent with DFNB16. Among 10 patients with LOH >1 Mb, we identified a single heterozygous mutation, indicating that at least small stretches of LOH are not useful predictors of homozygous STRC mutations. Among 20 patients without heterozygous deletion or LOH, one exhibited biallelic mutations. Although microdeletions are the most frequent mutation type, Sanger sequencing for the detection of point mutations or smaller intragenic deletions/duplications is mandatory in all SNHL patients displaying appropriate DFNB16 audiogram configurations.

There are different methods for STRC CNV detection. Multiplex ligation-dependent probe amplification (MLPA) (10) and qPCR successfully distinguish copy numbers, but are limited to small non-homologous regions harboring divergent nucleotides. The Illumina SNP array employed here covers STRC with seven single-nucleotide polymorphism (SNP) probes (three of them lacking 100% identity with pSTRC), which is conducive to CNV detection using standard diagnostic reporting algorithms. Array CGH similarly shows adequate resolution to detect a 45 kb deletion.

One previous study (9) employed a Sanger sequence approach to detect small sequence changes, but was unable to differentiate the STRC gene from the pseudogene, which is a drawback we have overcome. There are limited divergent nucleotides between STRC and pSTRC toward the 3’ portion of the gene. The absence of these in our LR exon 12–29 sequences confirmed specificity. In addition, we implemented an LR-PCR control in intron 18, whereby a three-nucleotide frameshift is present if pSTRC is amplified. This control verifies pseudogene exclusion for each LR-PCR, since this region overlaps with both LR products. This is important because pSTRC amplifies with unoptimized annealing temperatures and unintended gDNA carryover.

Interpretation is especially challenging for STRC analysis since we cannot rely on customary mutation and allele frequency data. Thousand Genomes Project and dbSNP index variants from Next Generation
Fig. 2. Bilateral pure tone audiograms from individuals with biallelic STRC mutations. Above the audiograms are the patient number, sex, and age. Circles in the audiograms represent the right, and crosses, the left ear, respectively. If multiple audiograms were present, an age range is listed and the average of all thresholds is depicted. Created with AUDIOMAKER software (http://www.jacobhaskins.com/).
Table 2. Audiological, clinical and family histories of biallelic STRC mutation patients

| No. | Onset | Audiological description<sup>a</sup> | Clinical description | Family history of HL |
|-----|-------|----------------------------------|---------------------|---------------------|
| 1   | 2 years | HL in all frequencies with mild HL in low- to mid-frequencies until 4 kHz, moderate to severe HL to 8 kHz | No additional symptoms | None; parents are confirmed heterozygous deletion carriers |
| 2   | Childhood | High tone HL, no further description available | Delayed speech and language development | Sister has HL since birth; two additional sisters are without HL; maternal grandmother and paternal grandfather have reported age-related HL |
| 95  | Birth | Auditory brainstem response measurements from the newborn hearing test indicated maximal thresholds of 65 dB | Born in the 35th week of gestation presenting facial dysmorphisms (long eye lashes, flat nasal bridge, and epicanthus), hypoplastic widely spaced nipples, atrial septal defect, and delayed speech development; also diagnosed with hydroxylysinsuria, hydroxylysinemia, and severe recurrent infections | No family history of HL; parents are first-degree cousins and confirmed heterozygous deletion carriers; one sibling died at 3 months because of an infection of unknown etiology |
| 3   | 5 years | Audiogram from age 10 indicated moderate HL, mildly sloping at higher frequencies | Oral motor skills and vocabulary developed normally per age; bifid uvula and sigmatism interdentalis diagnosed at 5 years of age; underwent intensive ambulant therapy for 1 year for dyslalia | Family history of HL |
| 4   | 3 years | High frequency HL with normal hearing thresholds until 1 kHz and mild to moderate HL from 2 to 8 kHz | None available | None |
| 6   | Birth | Mild to middle grade HL; free field and PTA between 2 and 4 years of age demonstrated mild HL in all frequencies and sloping audiometric profiles, more pronounced between 2 and 8 kHz | Hypothyroidism with HL prompted Pendred syndrome screening with SLC26A4 mutation negative result | None |
| 24  | 6 years | PTA with sloping high frequency configuration in the right ear and cookie bite pattern in the left ear | No additional symptoms | Father and paternal uncle have mild HL; parents are first-degree cousins with two additional normally hearing children |

HL, hearing loss; PTA, pure tone audiometry.
<sup>a</sup>All patients are bilaterally affected.

Sequencing (NGS) platforms that generate amplicon libraries indiscriminate of pseudogene counterparts. A well-rounded approach for STRC mutation assessment calls for consideration of evolutionary conservation of variants (18), as well as utilizing audiograms as helpful diagnostic tools, since high-frequency sloping appears a uniting feature of DFNB16. The c.3893A>G variant, which is predicted to be deleterious, was found with comparable MAFs (around 10%) in SNHL individuals and controls. Although we cannot entirely exclude the formal possibility that c.3893A>G in conjunction with an STRC deletion or pathogenic mutation contributes to SNHL, it should be considered as non-pathogenic as long as functional analyses are missing.

Conclusions

Our data confirm that STRC biallelic mutations significantly contribute to NSHL, particularly in children with mild to moderate hearing impairment with greater affection in higher frequencies. The frequency of DFNB16 in children with NSHL may be even higher than 6%...
STRC as a major contributor to hearing loss

information and sequence analysis assistance. We thank Dr Tom Muller from the University of Arizona, Dr Ian Krantz and Dr Lauren Francey from the Children’s Hospital of Philadelphia for their constructive discussion.
