Selective arterial embolization in hepatic trauma

Fred John, Mary Rithu Varkey

ABSTRACT

Introduction: Blunt abdominal trauma accounts for about (80%) of abdominal injuries seen in the emergency department. The spleen and liver are the most commonly injured solid organs in a blunt abdominal trauma. There has been a change in the trend towards the conservative management of liver injuries with improvement of the imaging techniques. Nowadays non-operative management has been preferred as the treatment of choice in hemodynamically stable cases of liver injuries. Transarterial embolization has been introduced as an effective tool for the management of hemodynamically stable patients with blunt hepatic trauma. This case illustrates the potential benefits of using hepatic artery embolization technique as a treatment modality in patients in whom active surgical intervention was not successful.

Case Report: A 21-year-old male presented to the emergency department with alleged history of fall from a building. On examination the patient was conscious and oriented, hypotensive, tachycardia and generalized abdominal tenderness. Focused assessment with sonography for trauma (FAST) was positive. So an emergency ultrasonography and contrast-enhanced computed tomography (CECT) scan of the abdomen were done which revealed gross hemoperitoneum with liver lacerations. Patient underwent an exploratory laparotomy, the surgeon was not able control the bleeding. So the patient was shifted to cath lab for an emergency hepatic artery embolization with gel foam. Bleeding was controlled with the procedure and he was discharged after two weeks.

Conclusion: The non-operative management of blunt hepatic trauma is considered to be the gold standard care for hemodynamically stable patients. Since angiography can offer both diagnostic and therapeutic benefits, angiography should be considered in localizing the site of hemorrhage and in providing an opportunity for the interventional radiologist to proceed to transcatheter embolization of bleeding sites.
Selective arterial embolization in hepatic trauma

INTRODUCTION

Blunt abdominal trauma accounts for about (80%) of abdominal injuries seen in the emergency department [1]. The spleen and liver are the most commonly injured solid organs in a blunt abdominal trauma [2–4]. Motor vehicle collision is one of the most common mechanism of injury in an abdominal trauma [5]. The large size of the liver, its position and the friable parenchyma, makes it prone to blunt injury. Right lobe is more often involved in trauma. The management of blunt hepatic trauma remains a topic of debate. The management of blunt abdominal injuries has changed dramatically over the last 25 years [6]. In the past decade, surgical interventions such as
arterial ligation, omental packing, liver resection, Pringle manoeuvre, etc. were done in cases of liver injuries, and the mortality was high. Recently, there has been a change in the trend towards conservative management of liver injuries with the advanced imaging techniques. Nowadays non-operative management has been preferred as the treatment of choice in cases of hemodynamically stable patients with blunt hepatic injury. Transarterial embolization has been introduced as an effective tool for the management in hemodynamically stable patients with higher grade injuries or evidence of contrast blush [7]. This case report illustrates a severe blunt hepatic injury successfully managed non-operatively using transarterial embolization.

CASE REPORT

A 21-year-old male presented to the emergency department with alleged history of fall from height of about 10 feet three hours back. The patient was fully conscious and oriented with patent airway and normal breathing and ventilation. On examination, hypotensive (blood pressure 70/50 mmHg), tachycardia (110 bpm) and generalized abdominal tenderness were found. Focused assessment with sonography for trauma (FAST) was positive. So an emergency ultrasonography and contrast-enhanced computed tomography (CECT) scan of the abdomen were done which confirmed significant hemorrhage consistent with a grade III injury by the American Association for the Surgery of Trauma Organ Injury Scale. The patient was resuscitated and shifted to the operation theatre for an exploratory laparotomy, laceration of 4x2 cm with active hemorrhage were noted, the surgeon was not able control the hemorrhage successfully. So the patient was shifted to cath lab. An angiogram of superior mesenteric artery (SMA) showed bleeding from accessory hepatic artery (Figure 1). The diagnostic catheterization of accessory hepatic artery, followed by gel foam infusion to the accessory hepatic artery (Figures 2 and 3). Figure 4 shows the distal part of accessory hepatic artery occluded. Figure 5 shows occluded right artery following embolization. Repeat arteriography confirmed the occlusion of the vessel. The patient was then transferred to the ICU and transfused one unit of whole blood. He remained hemodynamically stable thereafter, without significant decrease in hematocrit. The patient gradually improved over the next several days and was discharged after two weeks. Follow-up CT scan one month after discharge showed...
a mild hematoma with no evidence of any infection or complication of the embolization procedure.

**DISCUSSION**

The most common cause of liver injury is following a blunt abdominal trauma. Over the past few decades most of these cases were treated surgically. Studies have shown that as many as 80% of liver injuries have stopped bleeding by the time surgical exploration is performed [8]. With advanced imaging techniques such as CT scan, have made a great impact on the treatment and marked reduction in the number of patients requiring surgery. Computed tomography scan helps to localize the site and extent of injury. Hepatic artery angiography should be used when CT scan suggests an intrahepatic arterial bleed or high-grade injury in the management of hepatic injuries [9]. Selective arterial embolization of blunt hepatic trauma is considered to be the gold standard care for hemodynamically stable patients with higher grade injuries or the evidence of contrast blush visible in CT scan [10, 11]. It is considered as a conservative management as well as adjunct to surgery in cases of severe injury [12].

A history of blunt trauma of abdomen should always raise a suspicion of liver injury. Most common presentation would be a right upper quadrant tenderness, guarding and rebound abdominal tenderness. Even though there are no specific laboratory tests for hepatic injury. Some studies have been reported that patients with ALT and AST greater than two times normal should be assumed to possess major hepatic trauma [13]. The degree of anemia is based on the volume of blood lost. Earlier diagnostic peritoneal lavage (DPL) were done. Diagnostic peritoneal lavage is non-specific and invasive, time consuming, and oversensitive to presence of blood resulted in higher rate of non-therapeutic laparotomies. The DPL has been replaced by ultrasonography. The focused assessment sonography in trauma (FAST) is non-invasive which can be performed easily.

An emergent operative intervention is required in cases of hemodynamically unstable patients and severe grades of injury [14, 15]. Damage control surgery is done for the treatment of major liver injuries with significant survival advantages compared to traditional prolonged surgical techniques. Here perihepatic packing and closure of the abdominal incision is done either using a Bogota bag or partial closure of proximal abdominal incision. Kreig et al. recommend six folded laparotomy pads to be placed between the liver and the abdominal wall to provide a tamponade [16]. The patient is then resuscitated and stabilized and later under goes re-exploration surgery once all metabolic parameters are corrected. The timing of re-exploration depends upon the correction of acidosis, coagulopathy. Usually, 24 hours period for re-exploration surgery.

Hepatic embolization appears to be most successful when in hemodynamically stable patients who demonstrate extravasation of contrast on the initial abdominal CT scan. In this procedure, a catheter is introduced into the hepatic artery and a dye is injected which helps to locate the site of hemorrhage and then embolic particles are injected to plug the bleeding vessel. Depending upon the nature of the injury and technical factors Stent graft, embolization coils, microspheres, absorbable gelatin sponge, used to control the hemorrhage. Stent graft can be used only in arteries with a straight course which limits its use in tortuous or bifurcating arteries. Embolization can also be done
with coils, gel foam, etc. coil embolic works by inducing thrombosis in proximal part of vessels, the disadvantage is that repeat intervention is not possible, once blocked the portion distal to the block cannot be accessed. Gel form is a temporary embolic agent to seal active bleeding quickly and it gets absorbed by body and therefore the vessel recanalize in three weeks.

Pitfalls may arise, anatomical variation may occur in visceral vasculature. So one should anticipate aberrant arteries during the procedure. An initial angiogram would help to rule out any anomalies. In some patients, while on embolization may have a temporary vasospasm of the bleeding vessels ceasing the hemorrhage for a while which can misinterpreted by the surgeon and may lead to delayed hemorrhage. Many complications have been reported following non-operative transarterial embolization for liver injuries with bleeding. Fever is commonly seen in about 60% of patients who undergo embolization procedure [17]. Many patients experience a post-embolization syndrome which includes abdominal pain, fever, and ileus. Some cases of cholecystitis, and pancreatitis have also been reported in the embolization of the cystic or gastroduodenal arteries. Others include liver abscess, inadvertent embolization of other organs, contrast nephropathy and allergic reaction to contrast dye. The most dangerous complications of embolization are liver abscess and major hepatic necrosis [18]. Major hepatic necrosis can be managed with a series of operative debridements or with hepatic lobectomy, However, hepatic lobectomy was found to associate with a lower complication rate [19].

CONCLUSION

Selective arterial embolization has reduced mortality in cases of hepatic trauma. The non-operative management of blunt hepatic trauma is considered to be the gold standard care for hemodynamically stable patients. Angiography can offer both diagnostic and therapeutic benefits. It should be considered in localizing the site of hemorrhage and in providing an opportunity for the interventional radiologist to proceed to transcatheter embolization of bleeding sites. An emergent operative intervention must be considered in cases of hemodynamically unstable patients and severe grades of hepatic injury.

Edorium Journals: An introduction

Edorium Journals Team

About Edorium Journals
Edorium Journals is a publisher of high-quality, open access, international scholarly journals covering subjects in basic sciences and clinical specialties and subspecialties.

Invitation for article submission
We sincerely invite you to submit your valuable research for publication to Edorium Journals.

But why should you publish with Edorium Journals?
In less than 10 words - we give you what no one does.

Vision of being the best
We have the vision of making our journals the best and the most authoritative journals in their respective specialties. We are working towards this goal every day of every week of every month of every year.

Exceptional services
We care for you, your work and your time. Our efficient, personalized and courteous services are a testimony to this.

Editorial Review
All manuscripts submitted to Edorium Journals undergo pre-processing review, first editorial review, peer review, second editorial review and finally third editorial review.

Peer Review
All manuscripts submitted to Edorium Journals undergo anonymous, double-blind, external peer review.

Early View version
Early View version of your manuscript will be published in the journal within 72 hours of final acceptance.

Manuscript status
From submission to publication of your article you will get regular updates (minimum six times) about status of your manuscripts directly in your email.

Our Commitment

Six weeks
You will get first decision on your manuscript within six weeks (42 days) of submission. If we fail to honor this by even one day, we will publish your manuscript free of charge.

Four weeks
After we receive page proofs, your manuscript will be published in the journal within four weeks (31 days). If we fail to honor this by even one day, we will publish your manuscript free of charge and refund you the full article publication charges you paid for your manuscript.

Mentored Review Articles (MRA)
Our academic program “Mentored Review Article” (MRA) gives you a unique opportunity to publish papers under mentorship of international faculty. These articles are published free of charges.

Favored Author program
One email is all it takes to become our favored author. You will not only get fee waivers but also get information and insights about scholarly publishing.

Institutional Membership program
Join our Institutional Memberships program and help scholars from your institute make their research accessible to all and save thousands of dollars in fees make their research accessible to all.

Our presence
We have some of the best designed publication formats. Our websites are very user friendly and enable you to do your work very easily with no hassle.

Something more...
We request you to have a look at our website to know more about us and our services.

We welcome you to interact with us, share with us, join us and of course publish with us.
