Abstract

A novel exact dynamical real space renormalization group for a Langevin equation derivable from a Euclidean Gaussian action is presented. It is demonstrated rigorously that an algebraic temporal law holds for the Green function on arbitrary structures of infinite extent. In the case of fractals it is shown on specific examples that two different fixed points are found at variance with periodic structures. Connection with growth dynamics of interfaces is also discussed.

I. INTRODUCTION

Dynamical Renormalization Group (DRG) analyses of the critical dynamics of statistical mechanics models has a long history \[1,2,3\] with virtually all studies on regular translationally invariant structures. These approaches were, both in real and in momentum space, of a perturbative nature; in contrast, the principal aim of the present paper is the implementation of an exact approach, in real space, for the dynamics occurring on fractal structures.

Consider a system described by a Hamiltonian (or action) \( H(\{\varphi\}) \) with the field variables \( \varphi_x \) defined on the lattice sites \( x \). The simplest Langevin \[1\] dynamics leading to equilibrium with the correct Boltzmann weight \( \exp[-H(\{\varphi\})] \) is \[4\]:

\[
\frac{\partial \varphi_x(t)}{\partial t} = -\frac{\delta H(\{\varphi\})}{\delta \varphi_x} + \eta_x(t). \tag{1}
\]

The temperature has been absorbed in the definition of \( H \). The stochastic noise \( \eta_x(t) \) is chosen from a Gaussian distribution

\[
P(\{\eta(t)\}) = \mathcal{N}^{-1} \exp\left(-\sum_x \int d\tau \frac{\eta_x^2(\tau)}{4D}\right) \tag{2}
\]

(\( \mathcal{N}^{-1} \) is a normalization factor) which has a zero average and variance \( \langle \eta_x(t)\eta_{y}(t') \rangle = 2D \delta_{x,y} \delta(t-t') \).

We consider the simplest possible choice of the Hamiltonian \( H(\{\varphi\}) \), the Gaussian model:

\[
H(\{\varphi\}) = \sum_x a_x \varphi_x^2 - \sum_{<xy>} \varphi_x \varphi_y, \tag{3}
\]

where \( a_x \) depends on temperature and the scale of \( \varphi_x \) is such that the second term in (3), i.e. the sum over nearest neighbour sites, has coefficient 1.

Besides being the starting point of more complicated models, the Gaussian model is related to many physical situation such as the properties of an ideal polymer in solution \[5\], diffusion processes and the growth dynamics of interfaces \[6\]. Indeed if \( a_x = k^{-1} \) for any \( x \), then the hamiltonian \( (3) \) describes equilibrium properties of an ideal linear polymer in solution with a monomer fugacity equal to \( k \). In \( a_x = z_x \), the coordination number of site \( x \), the hamiltonian \( (3) \) can be rewritten as:
\[ H = \frac{1}{2} \sum_{<x,y>} (\phi_x - \phi_y)^2 \]  

and it is related to the diffusion process known as the ant in the labyrinth \cite{5,7}.

If \( \phi_x \) represents the height of an interface above the substrate point \( x \) (in the solid-on-solid approximation), then eq. (3) can be interpreted as the energy of an interface and the Langevin eq. (1) describes its dynamics. In a regular (hyper)cubic lattice this is known as the Edward-Wilkinson model for interface dynamics \cite{6}.

We shall show, in specific examples, that in the presence of non-translational structures (such as fractals) even the simple model (3) gives rise to interesting behaviours. Specifically we will show that two different fixed points are present unlike in structures with translational invariance where they collapse to the same fixed point. Part of the results presented here has already appeared in reference \cite{8}.

The paper is organized as follows. In Sec.II we introduce the DRG technique for this problem first in the simple case of a one-dimensional lattice and then in a situation in which the couplings have a hierarchical structure. In Sec. III the non-trivial cases of fractal structures with uniform and non-uniform coordination number are analyzed. In the latter case it will be shown that there is an additional universality class. Sec. IV contains both rigorous and heuristic arguments on a general network and for a non-linear case. The heuristic arguments are then checked by the numerical analysis of Sec. V. Finally in Sec.VI some closing conclusions are presented.

**II. ONE-DIMENSIONAL LATTICE**

We shall start with the simple case of a one-dimensional lattice. After a pedagogical example with uniform couplings, we will turn to a non-trivial example. In the latter case only DRG allows to obtain the asymptotic solution.
A. Uniform couplings

Let us start with a one-dimensional case in order to show how the method works. Equation (1) for the Hamiltonian (3) with \( a_x = a \) has then the form:

\[
\frac{\partial \phi_x(t)}{\partial t} = (\phi_{x-1}(t) + \phi_{x+1}(t) - a \phi_x(t)) + \eta_x(t)
\] (5)

It is immediately clear that if we were to choose uncorrelated noise, decimation would produce correlation between the nearest-neighbours noises. We thus assume a nearest-neighbour correlation to start with, that is:

\[
< \eta_x(t_1) \eta_y(t_2) > = 2D_{x,y} \delta(t_1 - t_2)
\] (6)

where \( D_{x,y} = D_0 \delta_{x,y} + D_1 \delta_{x \pm 1, y} \). As usual it is convenient to work in (time) Fourier space:

\[
\alpha \hat{\phi}_x(\omega) = \hat{\phi}_{x-1}(\omega) + \hat{\phi}_{x+1}(\omega) + \hat{\eta}_x(\omega)
\] (7)

where:

\[
f_x(t) \equiv \int_{-\infty}^{+\infty} \frac{d\omega}{2\pi} e^{i\omega t} \hat{f}_{x}(\omega)
\] (8)

and \( \alpha = a - i\omega \).

Upon decimation of (e.g.) the odd sites in favour of the even ones (i.e. solving eq. (5) for \( \hat{\phi}_{2x \pm 1} \) in terms of \( \hat{\phi}_{2x} \) and \( \hat{\phi}_{2x \pm 2} \)), we get an equation for the surviving (even) sites:

\[
(\alpha^2 - 2) \frac{\hat{\phi}_{2x}(\omega)}{\alpha} = \frac{(\hat{\phi}_{2x-2}(\omega) + \hat{\phi}_{2x+2}(\omega))}{\alpha} + \hat{\zeta}_{2x}(\omega)
\] (9)

where we have defined a new noise \( \hat{\zeta}_x(\omega) \) as

\[
\hat{\zeta}_{2x}(\omega) = \hat{\eta}_{2x}(\omega) + \frac{(\hat{\eta}_{2x-1}(\omega) + \hat{\eta}_{2x+1}(\omega))}{\alpha}
\] (10)

which is correlated as

\[
< \hat{\zeta}_x(\omega_1) \hat{\zeta}_y(\omega_2) > = 2\tilde{D}_{x,y}(2\pi) \delta(\omega_1 + \omega_2)
\] (11)

where as before \( \tilde{D}_{x,y} = \tilde{D}_0 \delta_{x,y} + \tilde{D}_1 \delta_{x \pm 1, y} \) and
\[ \tilde{D}_0 = D_0 \left(1 + \frac{2}{\alpha^2}\right) + D_1 \frac{4}{\alpha} \]  
\[ \tilde{D}_1 = D_0 \frac{1}{\alpha^2} + D_1 \frac{2}{\alpha} \]  

(12a)

(12b)

Therefore the new noise keeps the same correlation as the original one and being a linear combination of Gaussian noises is itself a Gaussian noise. With the redefinitions:

\[ \hat{\varphi}_{2x}(\alpha, D) = \alpha A \hat{\varphi}_x(\alpha', D') \]  
\[ \alpha' = \alpha^2 - 2 \]  
\[ \tilde{\zeta}_{2x} = A \hat{\eta}'_{x'} \]  

(13a)

(13b)

(13c)

the Langevin equation preserves its original form. The static recursions relation for \( a \) is obtainable from (13b) for \( \omega = 0 \), i.e.

\[ a' = a^2 - 2 \]  

(14)

from which the recursions equation for \( \omega \) is derivable. Indeed if \( \alpha = a - i\omega \), then \( \alpha' = a' - i\omega' \) with:

\[ \omega' = 2a\omega - i\omega^2 \]  

(15)

The variance of the new noise is \(< \hat{\eta}_x(\omega'_1) \hat{\eta}_y(\omega'_2) > = 2D'_{x,y}(2\pi)\delta(\omega'_1 + \omega'_2) \) with \( D'(\omega') = T(\omega) \cdot D(\omega) \). Here we have defined the \( 1 \times 2 \) matrix \( D = \begin{pmatrix} D_0 \\ D_1 \end{pmatrix} \) and \( T \) is the transmission matrix which, in the long time limit \( \omega \to 0 \) becomes:

\[ T = \frac{2a}{A^2} \begin{pmatrix} 1 + \frac{2}{a^2} & 4 \frac{1}{a} \\ \frac{1}{a^2} & 2 \frac{1}{a} \end{pmatrix} \]  

(16)

It is important to note that the amplitude \( A \), which is always allowed since it drops out from the final equations, is determined by the fixed point condition on \( D \). The critical fixed point of equation (14) is \( a^* = 2 \) (model (3) in 1-d is meaningful only for \( a \geq 2 \)). Since we are interested in critical dynamics, we will put \( a = a^* = 2 \) in what follows. By setting the determinant of the system giving the fixed point for the matrix \( D \) equal to zero
one obtains two solutions (two lines of fixed points corresponding to fixed ratios $D_0/D_1$) associated respectively to $A^* = 2^{1/2}$ and $A^* = 2^{3/2}$. It is easy to see that the first choice leads to an unstable solution while the second results in a stable one. Indeed, let $\Lambda_+$ and $\Lambda_-$ be the two eigenvalues of the transmission matrix $T$ and $u_+$ and $u_-$ the corresponding eigenvectors. Then if we start with an initial state $D$:

$$D = c_+ u_+ + c_- u_-$$  \hspace{1cm} (17)

($c_+$ being the coefficients of the expansion in the basis of eigenvectors) upon iteration of the RG transformation, the variance grows unbounded with the choice $A^* = 2^{1/2}$ while it is driven toward a stable fixed point $D^* = c_+ u_+$ with the choice $A^* = 2^{3/2}$.

We now have the means to compute the critical exponents of interest. From eq. (13a) we have, at the stable fixed point, for a generic scaling factor $b > 1$:

$$\hat{\varphi}_{bx}(\omega, D^*) = b^\phi \hat{\varphi}_x(b^z \omega, D^*)$$  \hspace{1cm} (18)

where $\phi = 5/2, z = 2$ is the dynamical exponent $z$ and we have written $\hat{\varphi}(\omega, D)$ instead of $\hat{\varphi}(2 - i\omega, D)$. The exponent $\phi$ can be related to the scaling of the two-point correlation function:

$$G_{x,y}(t_1, t_2) = <\varphi_x(t_1) \varphi_y(t_1)>$$  \hspace{1cm} (19)

where the average is over noise configurations. Using eq.(18), we get:

$$G_{bx,0}(t_1, t_2) = b^{2(\phi - z)} G_{x,0}(\frac{t_1}{b^z}, \frac{t_2}{b^z})$$  \hspace{1cm} (20)

The properties of the equal time correlation function can now be easily derived. If we define the function $W^2(L, t) \equiv G_{L,0}(t, t)$ we end up with the following scaling form:

$$W(L, t) = L^\alpha F(\frac{t}{L^z})$$  \hspace{1cm} (21)

with $\alpha = \phi - z = 1/2$ and $z = 2$. 

6
Few comments are in order. If $\varphi_x$ represents the height of an interface above the substrate site $x$, eq.(5), with $a = a^* = 2$ coincides with the growth equation proposed by Edwards and Wilkinson [6] with unit surface tension $\nu$, namely:

$$\frac{\partial \varphi_x(t)}{\partial t} = \nu \nabla^2 \varphi_x(t) + \eta_x(t)$$

(22)

where $\nabla^2$ is the discrete laplacian defined as

$$\nabla^2 \varphi_x = \sum_{y(x)} (\varphi_y - \varphi_x)$$

(23)

Here notation $y(x)$ means that the sum is restricted to the nearest neighbours of $x$. Then $W(L, t)$ coincides with the width of the interface which, as a function of time and of the lateral extent of the substrate $L$, is found to exhibit the general scaling form \[ W(L, t) \propto L^\alpha f(t/L^z) \], which reduces to $W(L, t) \propto t^\beta$ for $t << L^z$ and to $W(L, t) \propto L^\alpha$ for $t >> L^z$, where $\alpha = \beta z$ and $z$ is the standard dynamical exponent [1].

For a $d$-dimensional substrate Edwards and Wilkinson [6] found $\beta = \max \left( \frac{2-d}{4}, 0 \right)$ and $z = 2$ with an upper critical dimension of 2. Above $d = 2$ the interface is almost flat with $\alpha = \beta = 0$. Our results on a one-dimensional case, thus coincide with the exact results. We shall now apply the same methodology to a non-trivial case.

**B. Hierarchical couplings**

A rather interesting case which lacks translational invariance and which can be solved only by RG techniques, is the case of a one-dimensional lattice where however the coupling between nearest-neighbours are hierarchically distributed as in Figure [1]. In the case of diffusion, those kind of models have already been studied [10,11].

In the present context we start from the modified Hamiltonian:

$$H(\{\varphi\}) = \sum_x \frac{a_x}{2} \varphi_x^2 - \sum_{<xy>} w_{x,y} \varphi_x \varphi_y$$

(24)

where $w_{x,y} = w_{y,x}$ have the hierarchical structure defined as follows (see Fig.1):
\[ w_{x,x-1} = w_{x-1,x} = \begin{cases} 
\epsilon_n & n \geq 1 \\
\epsilon_0 & = 1 
\end{cases} \tag{25} \]

where \( x = (2m + 1)2^n \) \((n, m = 0, 1, 2, \ldots)\) and \( w_{x,y} = 0 \) if \(|x - y| > 1\). The choice \( \epsilon_0 = 1 \) can be made without loss of generality by a proper rescaling of the time scale.

As in the previous example we will work at criticality. This corresponds to the choice \( a_x = \sum_{y=x \pm 1} w_{x,y} \), i.e.

\[ H = \frac{1}{2} \sum_{<x,y>} w_{x,y} (\varphi_x - \varphi_y)^2 \tag{26} \]

The implementation of the RG transformation closely follows the one used in the diffusion case \[\text{[10,11]}\] and it is based on the decimation of the sites indicated by a circle in Fig.1. Interestingly, due to the particular decimation scheme chosen, the minimal set of parameters for the variance which are invariant under RG transformation, is \( D_{x,y} = D_0 \delta_{x,y} + D_{1,2} \delta_{y,x \pm 1} \) where one uses \( D_1 \) (\( D_2 \)) if \( w_{x,y} = \epsilon_0 \) (\( \epsilon_n \)) respectively. In other words a single self-correlation but two different nearest-neighbour correlations are involved. The recursions turn out to be:

\[ \hat{\varphi}_{bz}(\omega, D) = A \frac{\alpha_1^2 - \epsilon_1^2}{\epsilon_1} \hat{\varphi}_x(\omega', D') \tag{27a} \]

\[ \epsilon'_n = \epsilon_{n+1} \frac{\alpha_1^2 - \epsilon_1^2}{\epsilon_1} \quad (n = 1, 2, \ldots) \tag{27b} \]

\[ \omega' = \frac{2(1 + 2\epsilon_1)}{\epsilon_1} \omega + 0(\omega^2) \tag{27c} \]

\[ A \hat{\eta}_{x'}(\omega') = \hat{\eta}_{x'}(\omega) + \frac{\hat{\eta}_{y_L}(\omega)\epsilon_1 + \hat{\eta}_{y_R}(\omega)\alpha_1}{\alpha_1^2 - \epsilon_1^2} \tag{27d} \]

where \( \alpha_1 = -i\omega + 1 + \epsilon_1 \) and \( y_L(y_R) \) are left (right) sites which are decimated with respect to the barrier \( \epsilon_1 \). Apart from the noise contribution, the recursions are the same as in the case of diffusion \[\text{[10,11]}\]. It proves convenient to define \( R_n = \epsilon_{n+1}/\epsilon_n \) since, upon iteration of eq.(27d), it flows to a fixed point \( R \in (0,1] \) and then the analysis of the fixed points
is reduced to a study of a two-dimensional map in the \( \{ \epsilon_1, \omega \} \) plane. There are two fixed points \( O = (\epsilon_1^*, \omega^* = 0) \) and \( A = (\epsilon_1^* = R/(1 - 2R), \omega^* = 0) \) whose stability depends upon the value of \( R \). We will distinguish two cases:

A) \( R < 1/2 \) : \( A \) is stable and \( O \) is unstable and \( y = d_W = \ln(2/R)/\ln 2 \). The \( \omega \to 0^+ \) limit of the transition matrix \( T \) is

\[
T = (2/R)A^{-2} \begin{pmatrix}
    a(R) & b(R) & c(R) \\
   c(R) & d(R) & e(R) \\
    0 & 0 & 1
\end{pmatrix}
\]

where \( a(R) = 2(1 - R + R^2) \), \( b(R) = 2(1 - R) \), \( c(R) = 2R(1 - R) \), \( d(R) = 2R \), \( e(R) = 1 - 2R + 2R^2 \). The value of \( A^* \) which yields a stable fixed line is \( A^* = (4/R)^{1/2} \). Then, proceeding as in the previous example, one finds again \( \alpha = \frac{y - 1}{2} = \frac{|\ln R|}{2 \ln 2} \) as expected since in this case \( d_f = d = 1 \).

B) \( R > 1/2 \) : \( O \) is stable and \( A \) is unstable and then \( y = d_W = 2 \) as in the equal coupling case. The matrix \( T \) is

\[
T = 4A^{-2} \begin{pmatrix}
    \frac{3}{2} & 1 & \frac{1}{2} \\
   \frac{1}{2} & 1 & \frac{1}{2} \\
    0 & 0 & 1
\end{pmatrix}
\]

which yields \( A^* = 2^{3/2} \) (again as in the equal coupling case) and consequently \( \alpha = 1/2 \).

### III. FRACTALS

An interesting non-translationally invariant case, which can be analyzed with the technique described above, is the case of fractal structures. We will consider several examples which are prototypes of different physical situations.

**A. Fractals with uniform coordination numbers**

The first example is the standard Sierpinski Gasket shown in Fig. 3 whose fractal dimension is \( d_f = \ln 3/\ln 2 \). In this case, as on translationally invariant structures, there is only one fixed point. The renormalization group procedure is readily implemented in the Fourier transformed equation of motion (3) for the hamiltonian (3) which reads:
\[ \alpha_x \hat{\phi}_x(\omega) = \sum_{y(x)} \hat{\phi}_y(\omega) + \hat{\eta}_x(\omega) \quad (28) \]

where \( \alpha_x = a_x - i\omega \) and the sum is over nearest neighbours of \( x \). The set up for the noise is the same as in the one-dimensional case. As before we put directly \( a = a^* = 4 \) corresponding to the static fixed point. Then, following standard procedure, the RG transformation is carried out in two steps:

\textbf{a)} The \( \hat{\phi}_x \) on the circled sites in Fig. 2 are eliminated in order to rescale the system by a scale factor \( b \) (= 2 in this case). This may be done by solving Eq. (28) for \( \hat{\phi}_x(x = 1, 2, 3) \) in terms of \( \hat{\phi}_y \) (\( y = A, B, C \)) (see Fig. 2) and substituting the resulting equations back into (28).

\textbf{b)} \( \hat{\phi}_x \) and \( \hat{\eta}_x \) are then suitably rescaled as follows:

\[ \hat{\phi}_{x'}(\omega, D) = A(\omega + 6)\hat{\phi}_x(\omega', D') \quad (29a) \]

\[ A\hat{\eta}_{x'}(\omega') = (\omega + 5)(\omega + 2)\hat{\eta}_{x'}(\omega) + 2 \sum_{y(x')} \hat{\eta}_y(\omega) + (\omega + 4) \sum_{y((x'))} \hat{\eta}_y(\omega) \quad (29b) \]

and

\[ \omega' = \omega(5 - i\omega) \quad (29c) \]

where primed (unprimed) sites refer to the surviving (decimated) sites under the RG transformation, and \( y(x) \) and \( y((x)) \) are the decimated nearest-neighbours and the decimated next-nearest-neighbours respectively.

The procedure for calculating the amplitude \( A^* \) corresponding to the stable fixed point proceeds along exactly the same lines as the one-dimensional case: again the minimum set of parameters which are invariant under the RG transformation for the noise is \( \{D_0, D_1\} \) corresponding to the self and nearest-neighbour correlation respectively. It is noteworthy that the presence of noise does not influence the renormalization of time, thus prompting the identification of the dynamical critical exponent \( z \) with the fractal dimension \( d_W \) of the
walk on that structure giving the end-to-end distance $R(t)$ of the *ant in the labyrinth* at large $t$, i.e. $R(t) \sim t^{1/d_w}$. This is given by (29c) in the $\omega \to 0$ limit as $\omega' = b^{d_w}\omega$. One then finds the following critical exponents:

$$z = d_W, \quad \beta = \frac{2 - d_S}{4}, \quad \alpha = \frac{2 - d_S}{4}d_W = \frac{d_W - d_f}{2}$$

(30)

with $d_W = \ln 5/\ln 2$ and $d_S = 2d_f/d_W = \ln 9/\ln 5$ is the spectral dimension describing the low frequency behaviour of the density of vibrational modes [12,13]. A similar analysis can be carried out for a general d-dimensional Sierpinski Gasket.

**B. Fractals with non-uniform coordination number**

In the previous example we investigated the effect of the self-similarity of the structure on the scaling of the two-point correlation function for a Langevin equation induced by a Gaussian Hamiltonian. However in that example the coordination number was uniform (equal to 4) as in the translationally invariant lattice. The interplay between self-similarity of the substrate and non-uniformity of the coordination number has been recently investigated [14]. Contrary to what happens on periodic structures, it has been shown that on both statistical and deterministic fractal structures the equilibrium properties of (3) are governed by two universality classes, corresponding to ideal polymers and to the ant in the labyrinth [14]. We now study this effect on the Langevin equation on specific examples. The T-fractal (Fig.3) has $z_x = 1, 3$ whereas the Branching-Koch-Curve (BKC) (fig. 4) has $z_x = 2, 3$.

We stress again that the appearance of two fixed points is a feature of non-uniform coordination number and a fractal structure.

In the recursion relations we will derive below, the (minimum) set of parameters invariant under RG transformation is given by $D_{x,y} = D_{0z}$ if $x = y$ ($z$ is the coordination number), and $D_{x,y} = D_1$ if $x$ and $y$ are nearest neighbors and $D_{x,y} = 0$ otherwise. We will write $D = \begin{pmatrix} D_{01} \\ D_{03} \\ D_1 \end{pmatrix}$ and $\alpha = \begin{pmatrix} \alpha_1 \\ \alpha_3 \end{pmatrix}$. With this distinction in mind, calculations along the same lines as before, yield the following recursions:
\[ \tilde{\psi}_{bx}(\alpha, D) = A^\frac{\alpha_1 \alpha_3 - 1}{\alpha_1} \tilde{\psi}(\alpha', D') \]  

(31a)

\[ A\tilde{\eta}'_{x'}(\alpha') = \tilde{\eta}_{x'}(\alpha) + \sum_{y(x)} (\alpha_1 \tilde{\eta}_{y_1}(\alpha) + \tilde{\eta}_{y_3}(\alpha))/(\alpha_1 \alpha_3 - 1) \]  

(31b)

and

\[ \alpha'_1 = \alpha_1 \alpha_3 - 2 \]
\[ \alpha'_3 = \alpha_2 - \alpha_3/\alpha_1 - 3 \]  

(31c)

In the above definitions \( \tilde{\eta}_{y_1, y_3} \) represents the noise associated with sites of coordination 1 and 3 respectively.

In the static limit, \( \omega = 0 \), one has \( \alpha_x = a_x \) and as found in [14], the recursion equation (31c) admits two fixed points (see Fig 3): \( G = (a_1^*, a_3^*) = (1, 3) \), corresponding to the “ant in the labyrinth”, and \( P = (a_1^*, a_3^*) = (\infty, (1 + \sqrt{13})/2) \), describing the scaling behaviour of the ideal polymer [14]. (The symbols G and P denote growth and polymer respectively.) Indeed the linearized recursions (it is better to work with \( a_3 \) and \( a_3/a_1 \)) show that \( G \) is unstable (two relevant eigendirections) with a thermal exponent \( y_G = \ln 6/\ln 2 \), which coincides with \( d_W \) [12,13], the random walk dimension, while \( P \) is stable (one relevant and one irrelevant eigendirection) with \( y_P = \frac{\ln(1+\sqrt{13})}{\ln 2} \) related to the end-to-end distance \( R \) of an ideal polymer of length \( N \) according to \( N \sim R^{y_P} \).

Now let us turn to the dynamics. In the long time limit, i.e., \( \omega \to 0 \), and near the above static fixed points one has \( \alpha_x = a_x^* \). This implies that under renormalization \( \omega \) rescales as \( \omega(b) \sim b^y \omega \): thus the dynamical exponent \( z \) is equal to the thermal exponent \( y \) appropriate to the fixed point. From eq. (31b) one can easily calculate the new noise correlation functions near the fixed point. The recursion equation is:

\[ D' = T \cdot D \]  

(32)

with \( T = 6A^{-2} \left( \begin{array}{ccc} \frac{3}{2} & 1 & 1 \\ \frac{3}{2} & \frac{5}{4} & \frac{1}{4} \\ \frac{9}{2} & \frac{3}{4} & \frac{7}{4} \end{array} \right) \) at the fixed point \( G \) and \( T = 2a^{-1}A^{-2} \left( \begin{array}{ccc} 2a & 0 & a^2 \\ 2a & 1 & a^2 \\ 6a & 0 & 1 + 3a \end{array} \right) \) with \( a^{-1} = \frac{1+\sqrt{13}}{2} \) at the fixed point \( C \).
Thus, choosing the value of $A$ so that the largest eigenvalue is 1, one finds that the corresponding eigenvector $D^*$ is a stable fixed point. Near the fixed points from eq. (31a) one readily deduces the scaling of $\hat{\phi}_x(\omega, D^*)$ (we are writing $\hat{\phi}_x(a^* - i\omega, D^*)$) in the $\omega \to 0$ limit:

$$\hat{\phi}_b(x, D^*) = b^{a_z} \hat{\phi}_x(b^z \omega, D^*). \quad (33)$$

From (31a) and (33), one finds ($b = 2$)

$$\alpha_G = \frac{y_G - d_f}{2} = \frac{1}{2} \quad \text{at } G, \quad \alpha_P = \frac{y_P - 1}{2} = 0.601.. \quad \text{at } P \quad (34)$$

where $d_f = \ln 3/\ln 2$ is the fractal dimension of the structure. We will show below that the expression for $\alpha_G$ is completely general. Since $y_G = d_W$ and the spectral dimension, $d_S$, describing the low frequency behaviour of the density of vibrational modes satisfies the scaling relation \[d_S = 2d_f/d_W,\] the result (34) for $\alpha_G$ can be rewritten as $\alpha_G = \frac{2 - d_S}{4} d_W$. Taking into account that $z = d_W$ one gets $\beta = (2 - d_S)/4$.

An extension of the T-fractals to sites with coordination $z = 1, 4$ leads to exactly the same expressions as before with the same numerical value of $\alpha_G = 1/2$ with a slightly higher value $\alpha_P = 0.678...$ for the other fixed point. Thus the $\alpha_G$ is the same as in 1-d model of Sec. I.

A more interesting example because it is a structure with loops, is the case of the Branching-Koch-Curve (see Fig. 4). Calculations in this case are rather tedious but quite analogous to the previous example and we will omit annoying details. Also in this case it is sufficient to start with a variance $D_{x,y} = D_{0z} \delta_{y,x} + D_1 \delta_{|x-y|,1}$, where $D_{0z}$ is defined as before and with two a’s, $a_1$ and $a_2$ corresponding to two types of coordinations. At the fixed point $G = (a_2^* = 2, a_3^* = 3)$ one finds again $\alpha_G = (y_G - d_f)/2$ with $y_G = d_W = \ln(40/3)/\ln 3$ and $d_f = \ln 5/\ln 3$ consistent with the previous claim of a general form. The other fixed point $P = (a_2^* = +\infty, a_3^* = \sqrt{5})$ yields $y_P = \ln 11/\ln 3$ and $\alpha_P = \ln 2/\ln 3 = 0.6309...$. Notice that in the above example $\alpha_G \leq 1/2$ whereas $\alpha_P > 1/2$. 

13
IV. GENERALIZATIONS: GENERAL NETWORK AND NON-LINEARITY

Eq. (1) with \( D_{xy} = D \delta_{xy} \) evolves to an equilibrium state with a probability distribution for \( \{ \varphi \} \) given by:

\[
P_{eq}(\{ \varphi \}) \propto \exp \left\{ \frac{-\nu}{2D} \sum_{<xy>} (\varphi_x - \varphi_y)^2 \right\}
\]  

(35)

where \( x \) and \( y \) are nearest neighbor sites [15]. The equilibrium correlation function \( < (\varphi_x - \varphi_0)^2 >_T \) is defined as in eq. (19) calculated with the weight (35) can be shown [11] to be proportional to the resistance \( \Omega_{x,0} \) between two fixed sites 0 and \( x \) of the fractal network where conductances (equal to \( \nu/D \)) connect nearest neighbor sites that is:

\[
< (\varphi_x(t) - \varphi_0(t))^2 >_T \sim \Omega_{x,0} \sim |x|^\zeta
\]

(36)

where the last equality defines the exponent \( \zeta \) for the resistivity. Scaling arguments predict that for fractals \( \zeta = d_W - d_f \) (Einstein relation) [16]. Since the roughness exponent \( \alpha \) is defined by (see eq. [19,20] < (\varphi_x - \varphi_0)^2 >_T \sim |x|^{2\alpha} \), one finds \( \alpha = \frac{d_W - d_f}{2} = \frac{d_W(2-d_s)}{4} \). On the basis of the previous exact RG, we argue that the \( \omega \) renormalization (Eqs. (31) and (33)) is not influenced by the noise term in Eq. (1). We also note that Eq. (1) without the noise term is merely the diffusion equation with \( \varphi_x(t) \) interpreted as the probability of finding a diffusing particle at \( x \) at time \( t \). If \( \omega \) renormalizes as \( \omega' = b^2 \omega \) to leading order, then the mean square distance traveled after time \( t \) behaves asymptotically like \( t^{2/z} \) [11] implying \( z = d_W \).

We now show that the temporal behavior of the width of the interface \( W(t) \) for a substrate described by an arbitrary infinite network is also given by \( t^{(2-d_s)/4} \) (provided that \( d_s \) can be defined [17]). This is a non-trivial result since we prove not only that the temporal growth has a power law form, but also obtain the exponent. The proof is heavily based on the rigorous results of Hattori et al. (HHW) [18]. We assume as initial condition \( \varphi_x(t = 0) = 0 \). Let us go back to \( G_{xy}(t) = \langle \varphi_x(t) \varphi_y(t) \rangle \) where the average is over the noise as defined in Sec. IV. The formal (forward) solution of equation (22) can be written as:
\[ \varphi_x(t) = \sum_y \int_0^\infty d\tau U_{xy}(t - \tau) \eta_y(\tau) \quad (37) \]

where \( U_{x,y}(t) \) is the retarded Green function, associated to (22), satisfying:

\[ \left( \frac{\partial}{\partial t} - \nu \nabla_x^2 \right) U_{x,y}(t) = \delta_{x,y}\delta(t) \quad (38) \]

that is:

\[ U_{x,y}(t) = \theta(t)(e^{\nu \nabla_x^2})_{x,y} \quad (39) \]

where \( \theta(\cdot) \) is the step function.

Using (38), we have:

\[ G_{x,x_0}(t) = \langle \varphi_x(t)\varphi_{x_0}(t) \rangle = 2D \sum_y \int_0^t d\tau \ U_{xy}(t - \tau)U_{x_0,y}(t - \tau) \quad (40) \]

\[ = 2D \int_0^\infty U_{x,x_0}(2(t - \tau)) \]

where we have used the condition \(< \eta_x(t_1)\eta_y(t_2) > = 2D\delta_{x,y}\delta(t_1 - t_2)\).

Due to the initial condition \( U_{x_0,x}(0^+) = \delta_{x_0,x} \), then \( G_{x,x_0}(t) \) is a solution of:

\[ \left( \frac{\partial}{\partial t} - 4D\nu \nabla_x^2 \right) G_{x,x_0}(t) = \delta_{x,y}2D \quad (41) \]

It is then easy to verify that a probability \( P_{x,x_0}(t) \) defined through

\[ G_{x,x_0}(t) = \int_0^{4Dt} d\tau P_{x,x_0}(\tau) \quad (42) \]

is a solution of the diffusion equation

\[ \left( \frac{\partial}{\partial t} - \nu \nabla_x^2 \right) P_{x,x_0}(t) = 0 \quad (43) \]

The results of Ref. [18] can now be applied to Eq. (42) defined on the sites of an arbitrary graph. Since, under very general conditions, \( P_{x_0,x_0}(t) \sim t^{-d_s/2} \), from Eq. (42) we get:

\[ W^2(L, t)|_{L=\infty} = G_{x_0,x_0}(t) \sim t^{2\beta} \quad (44) \]

where \( \beta = (2 - d_s)/4 \) as expected from the previously solved cases.
From the same procedure one can recover also the exponent $\alpha$. Indeed if we assume the standard ansatz which appears to be valid for a generic fractal [19]:

$$P_{x,x_0}(t) = \frac{1}{t^{d_s/2}} \Phi(t|x - x_0|^{-y})$$

and using eq.(42) and (44) one finds $W(L,t) = L^{\alpha} f(t/L^z)$ with $\alpha = d_W(2 - d_S)/4$ as before (for $\alpha_G$ and $z = y$).

We now turn to non-linear growth on a fractal. We conjecture that the analog of the non-linear growth equation of reference [20] is given by:

$$\frac{\partial \varphi_x(t)}{\partial t} = \nu \sum_{y(x)} [\varphi_y(t) - \varphi_x(t)] + \lambda \sum_{y(x)} [\varphi_y(t) - \varphi_x(t)]^2 + \eta_x(t).$$

where now $\varphi_x(t)$ is to be interpreted as the height of the substrate at position $x$ at time $t$. The $\lambda$ term takes into account the lateral growth of the aggregate [20]. When $\lambda = 0$ we recover Eq. (22). Under rescaling of a factor $b$ of the length, the left hand side and the first two terms of the right hand side scale as $b^{\alpha - z}$, $b^{\alpha - d_W}$ and $b^{2\alpha - d_W}$ respectively, where $b^{-d_W}$ comes from the Laplacian on a fractal [21]. In the absence of the $\lambda$ term, dimensional analysis yields $z = d_W$, (found above) whereas the presence of the $\lambda$ term leads to the time derivative on the left hand side balancing the $\lambda$ term:

$$\alpha + z = d_W$$

with the $\nu$ term being subdominant. Eq. (47) generalizes the exact equation [24,25] for Euclidean lattices which are characterized by $d_W = 2$.

Additionally, following ref. [22], if we identify the dimension of the noise term to be $b^{-(z+d_f)/2}$ (this is expected to hold in the linear case where the $\lambda$ term is absent) and extending the dimensional analysis, we find again eq. (34) for $\alpha_G$.

In the presence of the $\lambda$ term, one may conjecture that the noise term scales as $b^{-(z+ad_c)/2}$ where $d_c$ is the chemical dimension of the fractal [22]. With this ad-hoc assumption one finds for equation (46):
\begin{align}
z = d_W \frac{2 + d_c}{3 + d_c}, \quad \beta = \frac{1}{2 + d_c}, \quad \alpha = \frac{d_W}{3 + d_c},
\end{align}

leading to: \( \alpha = 0.5064, \beta = 0.2789 \) in \( d = 2 \), and \( \alpha = 0.5170, \beta = 0.2500 \) in \( d = 3 \) Sierpinski gaskets. (For the gaskets in \( d \) dimensions \( d_c = d_f = \ln(d + 1)/\ln 2 \) and \( d_W = \ln(d + 3)/\ln 2 \)).

We stress the fact that Eq. (47) and (48) have been derived simply on the basis of power counting, and reduce to previously known approximations on translationally invariant structures [22,23].

V. NUMERICAL ANALYSIS

In order to verify Eq. (47) and check the conjecture leading to Eq. (48), we have carried out computer simulations of growth models on Sierpinski gaskets. We considered a sequence of sizes of gaskets in both two and three dimensions, the largest one containing 1095 and 2050 sites respectively. The value of \( \alpha \) was estimated by comparing the scaling of the saturated roughness with system size, whereas \( \beta \) was deduced by studying the temporal dependence of the roughness for the larger sizes. (i.e. \( W(L, t) \sim L^\alpha \) for \( t >> L^z \) and \( W(L, t) \sim t^\beta \) for \( t << L^z \)).

To check the correctness of the programs, we first studied the linear growth process in both \( d = 2 \) and \( 3 \) by adding and subtracting particles on the gasket sites with the same probability and found excellent agreement with the exact results of Eq. (34).

The nonlinear case was then studied by carrying out simulations of the Kim-Kosterlitz [23] growth model for the gaskets; the numerical results confirmed the validity of Eq. (47). Specifically we found: \( \alpha = 0.48 \pm 0.02 \) and \( \beta = 0.26 \pm 0.02 \) in \( d = 2 \), whereas \( \alpha = 0.48 \pm 0.02 \) and \( \beta = 0.23 \pm 0.02 \) in \( d = 3 \).
VI. DISCUSSIONS AND CONCLUSIONS

Our discussion so far has been restricted to growth on fractal substrates with the particles arriving along a space dimension orthogonal to that in which the fractal resides. One might also consider growth on a self-affine substrate (with no overhangs, so that all sites are accessible to the incoming particles) with the growth occurring in the direction normal to the rough surface, but yet in the $d$-dimensional hyperplane in which the surface resides. In this case, the resulting growth would be characterized by the regular exponents in $d - 1$ dimensions. This follows readily from two observations:

i) The exponent $\alpha$ characterizing the growth is a measure of the equilibrium roughness and does not depend on whether the initial configuration is a self affine or a planar interface.

ii) It is reasonable that the exponent $z$ which may be defined by studying the relaxation of small perturbations around equilibrium is typically the same that characterizes the approach to equilibrium from any initial configuration.

The exponent $\beta$ is deduced directly from $\alpha$ and $z$. Thus the growth exponents in this case are trivially determined.

Another observation is noteworthy. The results given here are valid for systems of continuous symmetry spins where, to the best of our knowledge, no analog of Henley’s argument, valid for Ising spins undergoing Glauber dynamics, [26] is known.

In conclusion we have presented a complete analysis of linear Langevin dynamics. The analysis has been carried out in real space and is based on a combinations of RG analysis, rigorous results and heuristic considerations.

The primary results of our dynamical RG analysis are:

1. For eq. (22), i.e. for linear growth processes, the width of the interface grows algebraically with time and the exponent $\beta = \frac{2-d_s}{4}$, where $d_s$ is the spectral dimension of the substrate. We stress that it is not common to explicitly demonstrate in a rigorous way such a power law behavior. Indeed, this result is valid not only for a fractal substrate, but for any generic substrate: $d_s$ can be rigorously defined [18] for almost all infinite graphs.
consisting of a set of nodes and links joining sites that are defined to be nearest neighbors.

2. For a fractal substrate, $z = d_W$, and $\alpha = \frac{2-d}{4}d_W$, where $d_W$ is the random walk dimension characterizing the asymptotic behavior of the root mean square distance, $R$, traveled after a time $t$, $R \sim t^{1/d_W}$.

$(d_W, d_s$ and the fractal dimension, $d_f$, are related by $d_s = 2d_f/d_W$ [27,12]).

3. For both fixed points of the hamiltonian (3) the dynamical exponent $z$ coincides with the thermal critical exponent $y$ of the corresponding static problem.

Result 1 is rigorous while 2 and 3 are based on exact arguments. For non-linear growth model (46), heuristic arguments and numerical analysis suggests that eqs. (48,47) are at least good approximations.
