ABSTRACT

We present Very Long Baseline Interferometry (VLBI) observations of 22 GHz H2O masers in the high-mass star-forming region of W75N, carried out with VLBI Exploration of Radio Astrometry (VERA) for three epochs in 2007 with an angular resolution of ~1 mas. The detection of H2O maser emission toward the radio jet in VLA 1 and the expanding shell-like structure in VLA 2. The spatial distribution of the H2O masers detected with VERA and measured proper motions around VLA 1 and VLA 2 are similar to those found with previous VLBI observations in epochs 1999 and 2005, with the masers in VLA 1 mainly distributed along a linear structure parallel to the radio jet and, on the other hand, forming a shell-like structure around VLA 2. We have made elliptical fits to the VLA 2 H2O maser shell-like structure observed in the different epochs (1999, 2005, and 2007), and found that the shell is still expanding eight years after its discovery. From the difference in the size of the semi-major axes of the fitted ellipses in epochs 1999 (±71 ± 1 mas), 2005 (±97 ± 3 mas), and 2007 (±111 ± 1 mas), we estimate an average expanding velocity of ~5 mas yr−1, similar to the proper motions measured in the individual H2O maser features. A kinematic age of ~20 yr is derived for this structure. In addition, our VERA observations indicate an increase in the ellipticity of the expanding shell around VLA 2 from epochs 1999 to 2007. In fact, the elliptical fit of the VERA data shows a ratio of the minor and major axes of ~0.6, in contrast with an almost circular shape for the shell detected in 1999 and 2005 (b/a ~ 0.9). This suggests that we are probably observing the formation of a jet-driven H2O maser structure in VLA2, evolving from a non-collimated pulsed-outflow event during the first stages of evolution of a massive young stellar object (YSO). This may support predictions made earlier by other authors on this issue, consistent with recent magnetohydrodynamical simulations. We discuss possible implications of our results in the study of the first stages of evolution of massive YSOs.

Key words: ISM: individual objects (W75N) – ISM: jets and outflows – ISM: kinematics and dynamics – masers – stars: formation

1. INTRODUCTION

In high-mass star-forming regions, H2O masers are locally generated and pumped by the interaction of supersonic outflows from a central young stellar object (YSO) with a clumpy medium (e.g., Elitzur 1992). Since H2O masers are bright and compact sources, they are one of the major targets for Very Long Baseline Interferometry (VLBI) with milliarcsecond (mas) angular resolution, as they are a powerful tool to know the structure and kinematics of the gas close to massive YSOs. In fact, VLBI and long-term monitoring observations of H2O masers have provided basic physical information for star-forming regions producing maser emission, revealing, for example, the internal structure of clusters of masers, the variability of their flux densities, radial velocities, proper motions, structure of the magnetic field, and evolutionary stages of massive protostars (e.g., Goddi et al. 2006; Surcis et al. 2011; Bartkiewicz & van Langevelde 2012; Chibueze et al. 2012; Torrelles et al. 2012; Vlemmings 2012).

W75N is a massive star-forming region located in the Cygnus X complex of dense molecular clouds (Dickel et al. 1978; Shepherd et al. 2003; Persi et al. 2006). The detection of H2O, OH, and CH3OH masers in the vicinity of the radio continuum sources VLA 1, VLA 2, and VLA 3 indicates that they are massive YSOs in their early stages of evolution, probably early B spectral types (Baart et al. 1986; Hunter et al. 1994; Torrelles et al. 1997; Shepherd et al. 2004; Surcis et al. 2009; Carrasco-González et al. 2010). These three sources are located within an area of ~1.5′ × 1.5′ (~3000 AU × d/2 kpc),11 with VLA 1 and VLA 3 showing elongated radio continuum emission interpreted as arising from radio jets, and VLA 2 showing compact unresolved continuum emission (<0″08) at centimeter wavelengths with a still unknown nature (Torrelles et al. 1997; Carrasco-González et al. 2010).

11 Most of the works published on W75N have been reported assuming a distance of 2 kpc (Fischer et al. 1985). However, a new estimate of 1.3 kpc for the distance has been recently reported through trigonometric parallax measurement (Rygl et al. 2012). All parameters given in this paper that depend on the distance are normalized to the distance of 2 kpc for proper comparison with results from previous works, but allowing accurate parameter estimates for the new reported distance of 1.3 kpc.
VLBI multi-epoch observations of H$_2$O masers carried out with the Very Long Baseline Array (VLBA) in 1999 show remarkably different geometries of outflow ejections in VLA 1 and VLA 2, with both objects separated by $\sim 0\text{.}7$ (1400 AU $\times [d/2\text{ kpc}]$; Torrelles et al. 2003, hereafter T03). In fact, the H$_2$O masers associated with VLA 1 are distributed along a linear structure parallel to its radio jet, with mean proper motions of $\sim 2$ mas yr$^{-1}$ (19 km s$^{-1}$ $\times [d/2\text{ kpc}])$, tracing a collimated jet-like outflow at scales of $\sim 1''$ (2000 AU $\times [d/2\text{ kpc}])$. On the other hand, the masers associated with VLA 2 display an almost circular shell-like structure of $\sim 0\text{.}08$ radius (160 AU $\times [d/2\text{ kpc}])$ around the central compact radio continuum source, moving outward in multiple directions with a mean proper motion of $\sim 3$ mas yr$^{-1}$ (28 km s$^{-1}$ $\times [d/2\text{ kpc}])$ and estimated kinematic age of 13 yr. T03 interpret this structure as a wind-driven shell from the central massive YSO. This result was surprising since the current paradigm of star formation through accretion disks, ejecting gas via magnetohydrodynamical (MHD) mechanisms, does not predict outflows expanding without any preferential direction, but producing collimated outflows (e.g., Garay & Lizano 1999; McKee & Tan 2002). On the basis of these VLBA results, T03 suggested that at the first stages of evolution of massive protostars there may exist short-lived events with very poorly collimated outflows. This has been theoretically proved very recently by Seifried et al. (2012), who performed MHD simulations of massive star formation by including both strong and weak magnetic fields. They found that at the earliest stage, in the case of a strong magnetic field, the outflows are poorly collimated for a short period. In addition, since the motions of the shell-like structure in VLA 2 are observed at a smaller scale than the collimated motions in the nearby VLA 1 source, T03 suggested that VLA 2 is in an earlier stage than VLA 1 and could evolve in the future into a collimated jet-like structure. More recently, Surcis et al. (2011, hereafter S11) compared the distribution of the masers around VLA 2 observed in 1999 (T03) and in a single epoch of 2005 (S11) and found an average expansion velocity for the shell-like structure of $\sim 4.8$ mas yr$^{-1}$ (46 km s$^{-1}$ $\times [d/2\text{ kpc}])$ over a time span of six years (1999–2005). In addition, these authors noted that there are preferential gas movements northeastward in the VLA 2 shell, suggesting the formation of a jet.

In this paper, we present three epochs of VLBI observations of H$_2$O masers in W75N carried out with the VLBI Exploration of Radio Astrometry (VERA) in 2007. The main goal of this work is to know the evolution of the expanding shell-like structure of VLA 2 by extending the timescale of the observations (1999–2007). In Section 2 we describe the VERA observations and data analysis, presenting the results in Section 3. In Section 4 we discuss the comparison of our results with those obtained from previous epochs of VLBI observations, focusing primarily on the evolution of the expanding H$_2$O maser shell-like structure of VLA 2. Their implications in the study of young massive protostars are also discussed. Our main conclusions are presented in Section 5.

2. OBSERVATIONS AND DATA ANALYSIS

The three epochs of H$_2$O maser line ($\delta_{16}$–$5_{23}$, 22235.080 MHz) observations toward W75N were carried out on 2007 January 20, 2007 February 21, and 2007 May 29 with VERA, a Japanese VLBI facility, including all four 20 m antennas. The baseline length of VERA ranges from 1019 km to 2270 km. All VERA antennas have a facility of dual-beam receiving systems (Haschick et al. 1981; Kawaguchi et al. 2000). The unique dual-beam mode enables us to carry out more effective phase-referencing VLBI observation than the conventional antenna in nodding mode, by simultaneously observing target and reference sources separated within 2$\prime$$2$. We utilized the dual-beam mode for W75N by taking the galactic radio continuum source Cygnus X-3. However, since the microquasar Cygnus X-3 is a transient source, we only detected fringes for the first and third epoch during its flaring states. As a result, it has not been possible to carry out the phase-referencing technique for W75N.

In each of the three epochs, the total observation time was 8 hr. All VERA stations had no systematic and technical problems. Left-handed circular polarization was received and sampled with two-bit quantization, and filtered using the VERA digital filter unit (Iguchi et al. 2005). The data were recorded onto magnetic tapes at a rate of 1024 Mbps, providing a total bandwidth of 256 MHz. We chose the VERA 7 mode in which one intermediate frequency (IF) was assigned to W75N and the other 15 IFs were assigned to Cygnus X-3. The well-known, bright continuum source BL Lac object was observed every 70 minutes for the bandpass and delay calibrations. The system noise temperatures including atmospheric attenuation, sensitive to weather conditions and the elevation angle of the observed source, were measured with the chopper-wheel method (Ulrich & Haas 1976). The aperture efficiencies of the antennas ranged from 45% to 52%, depending on each VERA station (see the VERA status report12). A variation of the aperture efficiency of each antenna as a function of the elevation angle was confirmed to be less than 10% at the lowest elevation in the observations around $\sim 20^\circ$.

Correlation processing was performed on the Mitaka FX Correlator (Chikada et al. 1991) located at the National Astronomical Observatory of Japan Mitaka campus. The accumulation period of the correlation was set to be 1 s. In the process of correlation, the bandwidth of the IF for W75N was reduced from 16 MHz to 8 MHz for H$_2$O maser line, divided by 512 channels of 15.625 kHz width, corresponding to a velocity resolution of 0.21 km s$^{-1}$. Therefore, the total velocity coverage is 107.5 km s$^{-1}$, centered at the local standard of rest (LSR) velocity $V_{\text{LSR}} = 12.3$ km s$^{-1}$.

Calibration and imaging were performed using the Astronomical Imaging Processing System (AIPS) of the National Radio Astronomy Observatory. The amplitude calibrations were performed based on the system noise temperatures during the observations. We used these data for the bandpass calibrations and the determination of clock and clock-rate offset. The Doppler shift due to Earth’s motion was corrected with the AIPS spectrum channel correction task, CVEL. The observed frequencies of the maser lines in each channel were converted to radial velocities with respect to the LSR using the rest frequency of 22.235080 GHz for the H$_2$O $\delta_{16}$–$5_{23}$ transition. For the three epochs of observations, the cross-correlation spectra of H$_2$O maser are shown in Figure 1. The cross-power spectra of all VERA baselines were checked to choose a single frequency channel of emission with unresolved structure and without rapid amplitude-time variation. The fringe-fitting process was carried out using the task FRING with an option of no delay search for the selected frequency channel. Using the IMAGR task, a synthesized image was made from fringe-fitted data with a 0.1 mas pixel for a region of 1024 $\times$ 1024 pixels, or $\sim 100 \times 100$ mas$^2$. Phase and amplitude self-calibrations were

12 http://veraserver.mtk.nao.ac.jp/restricted/CFP2010/status10.pdf
Figure 1. Example of scalar-averaged cross-power spectra of W75N observed with the VERA Mizusawa-Iriki baseline (1276 km). The black, green, and orange solid lines represent the observations on 2007 January 20, 2007 February 21, and 2007 May 29, respectively.

carried out based on a synthesized image as an initial model: a strong, point-like H$_2$O maser identified at $V_{\text{LSR}} \approx 7.9$ km s$^{-1}$ and associated with W75N VLA 2. For this maser we estimated absolute coordinates: $\alpha(J2000) = 20^h38^m36^s49 (\pm 0.01)$, $\delta(J2000) = 42^\circ37'34''3 (\pm 0.1')$.

As a result of the phase and amplitude self-calibrations, we obtained the complex gains that we applied to the rest of the frequency channels to produce the phase and amplitude-calibrated synthesized images in each channel. The resulting synthesized beams were $1.2 \times 0.8$ (first epoch), $1.2 \times 0.9$ (second epoch), and $1.4 \times 0.9$ (third epoch) in units of mas. To search for H$_2$O maser emission, a region of $2'' \times 2''$ was examined including VLA 1, VLA 2, and VLA 3. H$_2$O maser emission was detected toward VLA 1 and VLA 2, with typical rms values of $\sim 0.9$, and $0.3$ Jy beam$^{-1}$ for the first, second, and third epochs, respectively. In the first epoch, the relatively higher rms value is due to high system temperatures of $\sim 1000$ K and $\sim 800$ K in the Iriki and Ishigaki stations, respectively. To identify the H$_2$O masers, we adopted a signal-to-noise ratio $\geq 6$ as the detection threshold. The maser emission occurring at a given velocity channel and position (hereafter referred as maser spot) was fitted by two-dimensional elliptical Gaussian using the task JMFIT of AIPS to obtain necessary information such as the position, flux density, and radial velocity. The accuracy in the relative positions of the maser spots at each epoch is better than $\sim 0.1$ mas (estimated from the beam size and signal-to-noise ratio of the emission).

To measure the proper motions of the H$_2$O masers, an initial, preliminary alignment of the three epochs was made with respect to the reference maser spot used for self-calibrating the data. Within this reference system, we measured the proper motions of three masers that persisted in all three epochs through a linear fitting of their positions, and of 37 masers that appeared in two different epochs. To consider the persisting masers we applied the criterion of having the same radial velocity ($V_{\text{LSR}}$) in the different epochs and moving with proper motions within $\sim 10$ mas yr$^{-1}$ ($100$ km s$^{-1} \times [d/2 \text{ kpc}]$). However, the selected reference maser spot may have its own proper motion, introducing an arbitrary offset to the proper motions of all the masers. To minimize this effect, we subtracted the mean proper motion vector of all these 40 masers from the proper motion of each maser, making a realignment of the three epochs. The proper motion values of the 40 masers that we present in Table 1 have been obtained after this realignment.

3. RESULTS

We have detected two clusters of H$_2$O masers, one associated with VLA 1 and the other with VLA 2. No maser emission was detected toward VLA 3. In Figure 2, we present the spatial distribution of the masers in VLA 1 and VLA 2 as observed with VERA for three epochs in 2007. Globally, the maser distribution...
The H$_2$O maser emission in VLA 1 spans a radial velocity range from $V_{LSR} \sim 6$ to $13$ km s$^{-1}$, while that in VLA 2 is in the range of $0$ to $16$ km s$^{-1}$. We do not detect H$_2$O maser emission with $V_{LSR}$ lower than $0$ km s$^{-1}$, which was detected in the two previous VLBA observations in 1999 (T03) and 2005 (S11), probably due to the high flux density variability of the H$_2$O masers. With respect to the proper motion of the H$_2$O masers, we estimate the mean values of $\sim 2.1$ and $2.5$ mas yr$^{-1}$ ($\sim 20$ km s$^{-1}$ × $[d/2$ kpc] and $\sim 24$ km s$^{-1}$ × $[d/2$ kpc]) in VLA 1 and VLA 2, respectively (Figures 3 and 4; Table 1). These mean values are very similar to those obtained previously with the VLBA observations in 1999, $\sim 2$ and $3$ mas yr$^{-1}$, respectively (T03). In Section 3.1 we will concentrate on the

### Table 1

Notes.

$^a$ Position offsets of the masers are referred to the first epoch of detection. (0.0) corresponds to $\alpha$(J2000) = 20$^h$38$^m$36$^s$.94, $\delta$(J2000) = 42$^d$37$^m$34$^s$.3 ($\pm 0.1$).

$^b$ Proper motions of 1 mas yr$^{-1}$ correspond to 9.5 km s$^{-1}$ at 2 kpc distance. Uncertainty estimates for the proper motions of those masers detected in three epochs (linear fitting) are also given.

$^c$ o means detection and x means no detection.

is similar to that previously reported with VLBA in 1999 (T03) and 2005 (S11). In fact, while the H$_2$O masers in VLA 1 are mainly distributed along a linear structure parallel to its radio jet, the masers in VLA 2 are distributed in a shell-like structure surrounding the compact radio continuum source. The total H$_2$O maser spots detected with VERA are 31, 106, and 141, with most of the masers belonging to VLA 2, 25/31 (80%), 95/106 (90%), and 92/144 (64%) on 2007 January 20, 2007 February 21, and 2007 May 29, respectively. The probable reason for the relatively small number of detected masers in the first epoch is the higher rms level in this data set in comparison to the other two epochs (see Section 2). As a result, the shell-like structure associated with VLA 2 is not clearly seen in the first epoch (Figure 2).
H$_2$O maser shell-like structure detected around VLA 2 based on an elliptical fitting analysis, comparing our results with those from previous observations (T03, S11).

### 3.1. Ellipticity of the Shell-like Structure around VLA 2

From Figure 4, we see that the northeastern and southwestern parts of the shell-like structure as observed with VERA (epoch 2007) present proper motions mainly toward the northeastern and southwestern directions, respectively, with similar proper motion values ($\sim$3 mas yr$^{-1}$). The maximum angular separation from the northeastern and southwestern parts of the shell (those indicated in Figure 4 by labels B and D) is $\sim$220 mas, while the maximum angular separation within the shell observed in 1999 was $\sim$154 mas (T03). This increase in the angular separation between the tips of the shell in eight years (from 1999 to 2007) corresponds to an expanding velocity of $\sim$4 mas yr$^{-1}$ from the center. This expanding velocity is consistent with the proper motions measured in the individual masers of our three epochs of VERA observations in 2007 (Figure 4; Table 1).

To perform a more detailed study of the evolution of the shell-like structure, we have made elliptical fits to the H$_2$O maser positions detected with the VLBA in 1999 (April 2, May 7, and June 4; hereafter epoch 1999.3) and 2005 (November 21; hereafter epoch 2005.9), and with VERA (January 20, February 21, and May 29; hereafter 2007.2). The ellipses have been fitted by minimizing the chi-squared distribution of the distance measured from the position of the masers to the ellipse, along a line connecting the maser to the center of the ellipse. The main parameters of the elliptical fits, i.e., the semimajor (1) and semi-minor axes (2), and the position angle (PA), are listed in Table 2. In Figure 5 we show the position of the masers and the resulting fitted ellipses for epochs 1999.3 (ellipse T99), 2005.9 (ellipse S05), and 2007.2 (ellipse K07), plotted together assuming the same center position. We note that the
Figure 4. Position of the H$_2$O maser spots for all three epochs and measured proper motions of the masers in VLA 2. The vectors indicate the direction and values of the proper motions listed in Table 1. Sizes of filled circles and color codes are the same as those shown in Figure 2. Six groups of masers (A, B, C, D, E, and F) are shown close-up.

| Parameter of the Fitted Ellipses$^a$ |
|-----------------|-----------------|-----------------|-----------------|-----------------|-----------------|
| Name            | Epoch           | $a$             | $b$             | PA              | Expansion Velocity |
|                 |                 | (mas)           | (mas)           | ($\circ$)       | (mas yr$^{-1}$)  |
| T99             | 1999.3          | 71 ± 1          | 64 ± 1          | 5 ± 3           | T99–S05: 3.9 ± 0.8 |
| S05             | 2005.9          | 97 ± 3          | 93 ± 2          | 15 ± 45         | T99–S05: 37 ± 8   |
| K07             | 2007.2          | 111 ± 1         | 68 ± 1          | 45 ± 1          | S05–K07: 10.8 ± 3.1 T99–K07: 5.1 ± 0.2 |

Note. $^a$ Name of the fitted ellipse, observed epoch, semi-major and semi-minor axes, position angle, and expansion velocity are given in Columns 1, 2, 3, 4, and 5, respectively. The expansion velocity has been estimated from the difference in the semi-major axis size of the ellipse between different epochs. We note that the parameters of the elliptical fits we list in Table 2 differ slightly from those listed by S11 for epochs 1999.3 and 2005.9 due to an error in the algorithm used for the fitting in that previous paper.

Comparing the ellipses, we see that the semi-major axis has increased progressively over a time span of eight years, from 71 ± 1 mas in 1999.3 (ellipse T99), to 97 ± 3 mas in 2005.9 (ellipse S05), and to 111 ± 1 mas in 2007.2 (ellipse K07).
K07). This corresponds to expanding velocities in the intervals $T99–S05: 3.9 \pm 0.8$ mas yr$^{-1}$, $S05–K07: 10.8 \pm 3.1$ mas yr$^{-1}$, and $T99–K07: 5.1 \pm 0.2$ mas yr$^{-1}$. All these values for the expanding velocities are compatible among them for the given errors we estimated, although showing some indications that the shell has suffered an acceleration in the $S05–K07$ interval (see Figure 6). New epochs of VLBI H$_2$O maser observations are necessary to clearly confirm it.

Another relevant result is that the expanding H$_2$O maser shell-like structure has increased its ellipticity. In fact, the ratio of the semi-minor to semi-major axes of the fitted ellipse ($b/a$) for epoch 2007.2 is $\sim 0.6$, which is smaller than the one derived for the almost circular shells observed in epochs 1999.3 and 2005.9, $b/a \sim 0.9$ (see Figure 5). In addition, a more dominant axis of expansion appears along the northeast–southwest direction in epoch 2007.2 ($PA \sim 45^\circ$; Figures 4 and 5). We discuss the implications of our results in the study of the first stages of evolution of massive protostars in the next section.

4. DISCUSSION

In this section, we focus on the long-term evolution of the H$_2$O maser shell-like structure associated with the massive YSO VLA 2. Our VERA observations have extended the timescale in which this structure has been observed, by adding a third long-term epoch (2007.2) to the observations of T03 (epoch 1999.3) and S11 (epoch 2005.9), providing a solid result that the shell is still expanding in the plane of the sky at a velocity of $\sim 5$ mas yr$^{-1}$ ($47$ km s$^{-1} \times [d/2$ kpc]) eight years after its discovery.

The kinematic age of this expanding structure is $\sim 20$ years up to epoch 2007, a value in agreement with the kinematic age of 13 years estimated from the VLBA observations of epoch 1999.3 (T03), considering the eight years between these observations and our VERA observations. As discussed by T03, the most probable scenario for the origin of this H$_2$O maser structure is a wind-driven shell, for which they obtained a wind mass-loss rate ($\dot{M}_w/M_\odot$ yr$^{-1}$) = $8 \times 10^{-7}(n/10^8$ cm$^{-3})^{1/2}(T/500$ K)$^{1/2}$, terminal wind velocity ($V_w$/km s$^{-1}$) = $100(n/10^8$ cm$^{-3})^{1/2}(T/500$ K)$^{1/2}$ (where $n$ and $T$ are the particle density and temperature of the shell, respectively), and density outside the shell (molecular gas environment) ($n_0$/cm$^{-3}$) = $2.6 \times 10^5(n/10^8$ cm$^{-3})$. These are reasonable parameters for early B stars ($\dot{M}_w$, $V_w$) and molecular core ($n_0$). T03 and S11 also proposed that the ejected wind from the central massive object should be non-collimated (to explain the almost circular shape of the shell observed in epochs 1999.3 and 2005.9), as well as repetitive (to explain the short kinematic age of the shell).

Besides that, the H$_2$O maser structure continues to expand. Our VERA observations also indicate an apparent increase with time in the ellipticity of the shell, from an almost circular shape as observed in epochs 1999.3 and 2005.9, $b/a \sim 0.9$, to a more elliptical shape as observed in epoch 2007.2 ($b/a \sim 0.6$), with a more dominant expansion along an axis with PA $\sim 45^\circ$ (see Section 3, Figure 5 and Table 2). This result is consistent with the prediction made previously by S11, who noted that in epoch 2005.9 there are preferential gas movements northeastward, suggesting the formation of a collimated outflow.
in that direction (see H$_2$O maser positions of S11 at $\sim$[120, 80] mas in Figure 5). Furthermore, we found out that the previous proper motion measurements of the H$_2$O masers of the VLA 2 shell in epoch 1999.3 were already showing larger velocities in the plane of the sky along the northeast–southwest direction (see Figure 1 of T03). In the animation available in the online journal (see Figure 7 for a sample screenshot), we show the expanding motions of the shell as measured by T03 but extrapolated 10 years ahead starting in epoch 1999.3, where these main motions along the northeast–southwest direction are clearly seen. We think that this gives even more support to the northeast–southwest expansion direction of the shell in VLA 2.

Based on these results, we suggest that we are probably observing the formation of a collimated jet-driven H$_2$O maser structure, evolving from a non-collimated pulsed-outflow event during the first stages of evolution of a massive YSO. The PA of the newly forming jet in VLA 2 would be $\sim$45$^\circ$, which interestingly is similar to the PA of the nearby more evolved VLA 1 radio jet (PA $\sim$ 40$^\circ$; T03), being separated both YSOs by $\sim$0'7 ($\sim$1400 AU$\times$[d/2 kpc]). In addition, this PA is close to the direction of the large-scale magnetic field aligned to the large-scale bipolar molecular outflow in the region ($\sim$5', or $\sim$3 pc, PA $\sim$ 70$^\circ$; Shepherd et al. 2003; S11), but it is far from the average direction of the local magnetic field around VLA 2 ($\phi_{B}^{VLA2}$ $\sim$ 18$^\circ$; S11). Actually, the local magnetic field around VLA 2 shows a radial morphology consistent with the recent simulations of massive star formation (e.g., Seifried et al. 2012). This suggests that the local magnetic field in the region plays an important role in the early phases of the formation of the outflows but afterward the large-scale magnetic field starts to also dominate in VLA 2, even though S11 measured a stronger magnetic field around VLA 2 ($|B|_{\text{max}}^{VLA2}$ $\approx$ 1000 mG) than around VLA 1 ($|B|_{\text{max}}^{VLA1}$ $\approx$ 800 mG). To explain the evolution from a non-collimated outflow event to a collimated outflow in VLA 2, we speculate on the presence of a disk-like gas structure around this massive object, oriented southeast–northwest (perpendicular to the orientation of the local magnetic field in the region). In this scenario, an “isotropic” ejection event from the central source would expand more freely in the direction perpendicular to the disk-like structure, along the magnetic field lines. If this scenario works, it would imply that the disk-like structure has a central “hole” (cavity) of $\sim$60–90 mas radius, the size of the semi-minor axis of the shell. This scenario fits quite well with the three-dimensional MHD simulations performed by Seifried et al. (2012). They found that in the earliest stage of a massive star formation, the outflows are non-collimated if a strong magnetic field is present. Afterward, their collimation increases quickly due to the development of a fast, central jet coupled to the build-up of a Keplerian disk.

“Short-lived” pulsed ejections (some of them isotropic or non-collimated) have been observed through VLBI H$_2$O maser observations in different massive protostars, including W75N VLA 2. It is still unclear whether these are non-standard phenomena in particular types of sources, or if all massive protostars undergo short-lived pulsed ejection phases. Nevertheless, their presence provides new insights in the study of the formation of high-mass stars (e.g., Torrelles et al. 2001, 2011; Sanna et al. 2012; Trinidad et al. 2013). What we are observing now in W75N VLA 2 is the likely formation of a colli-

mated outflow from a non-collimated expanding shell, as theoretically expected from the MHD simulations of Seifried et al. (2012). However, we think that new epochs of VLBI H$_2$O maser observations, even in full polarization, are mandatory to confirm this tendency found with our VERA observations (including a possible acceleration in the shell). JVLA observations at centimeter/millimeter wavelengths would be very important to see if the central radio continuum source (VLA 2) has also evolved into an elongated structure along the northeast–southwest direction, like the nearby radio jet in VLA 1. High-angular resolution, sensitive (sub)mm observations to study the dust and molecular gas distribution around VLA 2 would also help us understand the evolution of this expanding shell.

5. CONCLUSIONS

We have carried out three epochs of VLBI observations of H$_2$O masers during 2007 toward the high-mass star-forming region of W75N with $\sim$1 mas of angular resolution, comparing our data with those previously obtained in 1999 and 2005. We find that the H$_2$O maser shell associated with the massive YSO VLA 2 is still expanding at $\sim$5 mas yr$^{-1}$ ($\sim$47 km s$^{-1} \times d/2$ kpc) eight years after its discovery in epoch 1999. The shell, with a current size of 222 mas $\times$ 136 mas (444 AU $\times$ 272 AU at 2 kpc) and kinematic age of $\sim$20 yr, shows a ratio between the minor and major axes of $\sim$0.6, in contrast with the almost circular shape of the shell observed in 1999 and 2005. These results would suggest that we are probably observing the formation of a jet-driven water maser structure, as previously proposed and consistent with recent MHD simulations of massive star formation by Seifried et al. (2012). These MHD simulations predict that at the earliest stage, the outflows are poorly collimated for a short period, evolving into a collimated outflow, as we are probably observing in VLA 2.

New epochs of VLBI H$_2$O maser observations are mandatory to confirm this tendency found with our VERA observations (including a possible acceleration in the shell).

We thank our referee for a very careful review of the manuscript, which has helped to substantially improve its content. J.C. acknowledges support from CONACyT (México) grant 61547. S.J.K. acknowledges partial supports from the Korea Science and Engineering Foundation (R01-2008-000-20002-0) and a WCU grant (No. R31-10016).
