Abstract: In order to obtain the adsorption mechanism and failure characteristics of CO\textsubscript{2} adsorption by potassium-based adsorbents with different supports, five types of supports (circulating fluidized bed boiler fly ash, pulverized coal boiler fly ash, activated carbon, molecular sieve, and alumina) and three kinds of adsorbents under the modified conditions of K\textsubscript{2}CO\textsubscript{3} theoretical loading (10%, 30%, and 50%) were studied. The effect of the reaction temperature (50 °C, 60 °C, 70 °C, 80 °C, and 90 °C) and CO\textsubscript{2} concentration (5%, 7.5%, 10%, 12.5%, and 15%) on the adsorption of CO\textsubscript{2} by the adsorbent after loading and the effect of flue gas composition on the failure characteristics of adsorbents were obtained. At the same time, the microscopic characteristics of the adsorbents before and after loading and the reaction were studied by using a specific surface area and porosity analyzer as well as a scanning electron microscope and X-ray diffractometer. Combining its reaction and adsorption kinetics process, the mechanism of influence was explored. The results show that the optimal theoretical loading of the five adsorbents is 30% and the reaction temperature of 70 °C and the concentration of 12.5% CO\textsubscript{2} are the best reaction conditions. The actual loading and CO\textsubscript{2} adsorption performance of the K\textsubscript{2}CO\textsubscript{3}/AC adsorbent are the best while the K\textsubscript{2}CO\textsubscript{3}/Al\textsubscript{2}O\textsubscript{3} adsorbent is the worst. During the carbonation reaction of the adsorbent, the cumulative pore volume plays a more important role in the adsorption process than the specific surface area. As the reaction temperature increases, the internal diffusion resistance increases remarkably. K\textsubscript{2}CO\textsubscript{3}/AC has the lowest activation energy and the carbonation reaction is the easiest to carry out. SO\textsubscript{2} and HCl react with K\textsubscript{2}CO\textsubscript{3} to produce new substances, which leads to the gradual failure of the adsorbents and K\textsubscript{2}CO\textsubscript{3}/AC has the best cycle failure performance.

Keywords: potassium-based adsorbent; load modification; CO\textsubscript{2} adsorption; failure; kinetics; microscopic characteristics

1. Introduction

Global climate change caused by greenhouse gas emissions is a hot issue in our modern society, which is related to the development and survival of the whole mankind. China’s carbon emissions account for 29% of the global total and rank first in the world [1]. The current CO\textsubscript{2} emission reduction technologies are mainly divided into four ways: pre-combustion decarbonization [2,3], chemical chain circulation [4,5], pure oxygen combustion [6,7], and post-combustion capture [8–11]. Among them, CO\textsubscript{2} capture and storage (CCS) technology has been widely used [12–15], but its cost is high [16,17]. However, alkali metal carbonates such as Na\textsubscript{2}CO\textsubscript{3} and K\textsubscript{2}CO\textsubscript{3} have become the promising CO\textsubscript{2} adsorbents due to their low cost, low secondary pollution, and high cycle efficiency [18,19].
It has been found that potassium-based adsorbents can remove CO\textsubscript{2} at a low temperature (60–80 °C) under the conditions in which water vapor is adsorbed [20]. However, its adsorption efficiency is low. Some researchers have modified the potassium-based adsorbent by using activated carbon (AC), MgO, TiO\textsubscript{2} [21], and a 5A molecular sieves [22] and studied the carbonation reaction by thermogravimetric analyzer. They found that the CO\textsubscript{2} adsorption rate of K\textsubscript{2}CO\textsubscript{3}/AC adsorbent increased by 73% as the AC loading increased from 9% to 33% under the conditions of 60 °C and 10% CO\textsubscript{2} [23]. When the Al\textsubscript{2}O\textsubscript{3} loading increased from 12.8% to 36.8%, the CO\textsubscript{2} adsorption rate of the K\textsubscript{2}CO\textsubscript{3}/Al\textsubscript{2}O\textsubscript{3} adsorbent increased by 62% [24]. However, the above studies only use the thermogravimetric analyzer to study the carbonation reaction process by the weight loss of the adsorbent. The mass of the adsorbent involved in the reaction is small and the range of loading is narrow.

Since the potassium-based adsorbent can be regenerated in the temperature range of 120 to 200 °C, it provides the possibility of an absorption-regeneration cycle of the adsorbent, which achieves the efficient removal of CO\textsubscript{2}. At the same time, the material composition and microstructure of fly ash in coal-fired power plants are very similar to those of activated carbon. Hence, the use of fly ash as a support can make up for the disadvantages of low utilization efficiency of fly ash alone and also modify the potassium-based adsorbent to improve the removal efficiency of CO\textsubscript{2}. However, due to the large difference between the combustion mode of pulverized coal (PC) and circulating fluidized bed boiler (CFB) and the fuel used, the chemical composition and microstructure of the fly ash produced are quite different.

In addition, the reaction and adsorption kinetics studies have become an important method for predicting the adsorption rate-determining step and analyzing the adsorption mechanism. It is widely used in the adsorption of heavy metals from the liquid phase and the adsorption of SO\textsubscript{2} and NO on the surface of solid adsorbents. At present, there are very limited studies on the adsorption kinetics, thermodynamics, and adsorption equilibrium of CO\textsubscript{2} on the surface of adsorbents.

In summary, the adsorption of CO\textsubscript{2} by potassium-based adsorbents is related to its characteristics and the focus of the above studies is scattered. Although there have been studies on the modification of potassium-based adsorbents by different supports, the related effects vary greatly depending on the type of support. Among them, the studies on the modification using fly ash as a support have rarely been reported. The study of adsorption kinetics of CO\textsubscript{2} by adsorbents is also relatively small and the relevant mechanisms are not fully explained. On the basis of different supports’ effects on the CO\textsubscript{2} adsorption characteristics of potassium-based adsorbents combined with the microscopic properties of the adsorbent, the mechanism of carbonation is studied using reaction and adsorption kinetics. Moreover, the effect of flue gas composition on the failure characteristics of the adsorbent is studied, which will provide a theoretical basis for future CO\textsubscript{2} removal methods.

2. Research Object and Method

2.1. Preparation and Characterization of Samples

K\textsubscript{2}CO\textsubscript{3} (Bodi chemical industry, Tianjin, China) was chosen as the active component of the adsorbent sample in this study and circulating fluidized bed fly ash (CFA) (Ping Shuo power plant, Pingshuo, China), pulverized coal furnace fly ash (PFA) (Datang Taiyuan Second Thermal Power Plant, Tai Yuan, China), activated carbon (AC) (Guang Fu Technology, Tianjin, China), 5A molecular sieve (5A) (Hua Kang, Gongyi, China), and γ-aluminum oxide (γ-Al\textsubscript{2}O\textsubscript{3}) (Heng Xing, Tianjin, China) were used as supports. The adsorbents were prepared by impregnating. The theoretical loading of K\textsubscript{2}CO\textsubscript{3} were selected 10%, 30%, and 50%, respectively. 100 g supports were added to an aqueous solution containing a certain amount of K\textsubscript{2}CO\textsubscript{3} (10 g, 30 g, and 50 g) in 500 mL deionized water. Then, it was stirred with a magnetic stirrer (Guang Ming, Beijing, China) for 10 h at room temperature. Thereafter, the mixture was dried in the oven (Gang Yuan, Tianjin, China) for 8 h at 105 °C. The dried samples were then calcined in a muffle furnace (Ke Jing, Zhengzhou, China) for 4 h at 300 °C. Lastly,
the samples were crushed and screened to a particle size range within 75 µm by the sieve shaker (Xin Da, Shaoxing, China) to get the final adsorbent.

The actual loading represents the ratio of the active component K$_2$CO$_3$ loaded on the support particles in the prepared adsorbent, which is shown in Equation (1). The theoretical and corresponding actual loadings of the five supports are shown in Table 1.

\[
L_R = \frac{m_f - m_i}{m_i} \times 100\% \tag{1}
\]

where $L_R$ is the actual loading, %; $m_f$ is the mass of the sample after loading, g; $m_i$ is the mass of the support particles, g.

**Table 1. Actual loading of different supports.**

| Theoretical Loading (%) | AC  | Al$_2$O$_3$ | 5A  | CFA | PFA |
|-------------------------|-----|-------------|-----|-----|-----|
| 10                      | 9.4 | 7.7         | 8.4 | 8.5 | 8.9 |
| 30                      | 28.6| 21.2        | 24.3| 26.2| 27.5|
| 50                      | 44.3| 32.5        | 37.5| 39.6| 41.3|

In addition, the content of the K element in the adsorbent was analyzed by ARL9800XP X-ray Fluorescence (XRF) (ARL, Berne, Switzerland) and a more accurate actual load was obtained. The results are shown in Table 2. It can be seen from the table that the actual loading calculated by the XRF characterization method is similar to the calculation result of Equation (1) and the results of this paper are verified.

**Table 2. Actual loading of different supports by XRF.**

| Theoretical Loading (%) | AC  | Al$_2$O$_3$ | 5A  | CFA | PFA |
|-------------------------|-----|-------------|-----|-----|-----|
| 10                      | 9.63| 7.68        | 8.45| 8.64| 8.91|
| 30                      | 28.72| 21.32      | 24.24| 26.27| 27.65|
| 50                      | 44.32| 32.45      | 37.73| 39.81| 41.36|

In order to obtain the microscopic characteristics of the prepared adsorbent, the N$_2$ adsorption and desorption experiments were carried out by ASAP 2460 analyzer (Micromeritics, Norcross, GA, USA). The specific surface area was calculated by the Brunauer-Emmett-Teller (BET) equation and the pore structure parameters of the adsorbent were obtained by the Barrett-Joyner-Halenda (BJH) method. The surface morphology of the adsorbent was obtained by the Nova Nano SEM 50 scanning electron microscopy (Thermo Fisher Scientific, Hillsboro, OR, USA) and the crystal structure of the adsorbent was obtained by the X/max-2500 X-ray diffractometer (XRD) (Rigaku, Tokyo, Japan).

### 2.2. Fixed Bed CO$_2$ Adsorption Experiment System

The fixed bed carbon adsorption experimental system is shown in Figure 1. It is mainly composed of a simulated gas production system, a reaction system, and a data acquisition and processing system. The simulated flue gas N$_2$/CO$_2$/H$_2$O in the experiment was provided by a gas distribution system in which the flow rate of water was controlled by a Series III metering pump (SSI, Cincinnati, OH, USA) and gasified into water vapor by electric heating. It was also thoroughly mixed with N$_2$/CO$_2$. During the carbonation reaction, the CO$_2$ concentration was monitored online by the MOT (Monitor) series gas detector (Keernuo, Shenzhen, China).
In the experiment of carbonation of adsorbent, 5 g adsorbent was placed in the reactor with a simulated flue gas volume of 500 mL (water vapor concentration is 10%). Since the reaction temperature range of carbonation is 50 to 90 °C, considering that the actual flue gas environment of the power plant, the reaction temperatures were selected as 50 °C, 60 °C, 70 °C, 80 °C, and 90 °C while the CO₂ concentrations were selected as 5%, 7.5%, 10%, 12.5%, and 15%, respectively. Furthermore, the CO₂ adsorption characteristics of the adsorbent were evaluated by the CO₂ adsorption rate \( \eta \) as shown in Equation (2).

\[
\eta = \frac{\Delta m}{2 \times M_{KHCO_3} \times m_{K_2CO_3}} \times 100\%.
\]  

where \( \Delta m \) is the weight gain of the sample during the reaction, g. \( M_{K_2CO_3} \) is the relative molecular mass of \( K_2CO_3 \), \( M_r = 138 \). \( M_{KHCO_3} \) is the relative molecular mass of \( HKCO_3 \) and \( M_r = 100 M_{K_2CO_3} \) is the mass of the adsorbent before the reaction, g.

Moreover, in order to obtain the failure characteristics of the adsorbents under different flue gas composition, the adsorbents sample adsorbed with CO₂ were filled into the fixed bed carbon adsorption experiment system as described above to perform multiple adsorption/regeneration cycle experiments. During the cycle experiment, NO (0.05%), SO₂ (0.05%), and HCl (0.05%) were added to the atmosphere of the carbonation reaction. Regeneration experiments were carried out in an N₂ atmosphere and the reaction temperature was 200 °C.

### 3. Results and Discussion

**3.1. Effect of Loading and Adsorption Conditions on Carbonation Reaction**

*3.1.1. Carbonation Reaction Characteristics of Adsorbents under Different Load Conditions*

In order to obtain the optimal loading of adsorbents of different support types, the carbonation reaction of the modified potassium-based adsorbents were carried out at 12.5% CO₂ and 70 °C. The results are shown in Figure 2.

Among all the adsorbents, the \( K_2CO_3/AC \) sample has the highest CO₂ adsorption rate under different loading conditions and the actual loading of \( K_2CO_3 \) in this adsorbent is also the largest. Among the different adsorbents, when the theoretical loading of \( K_2CO_3 \) is 10%, the adsorption rate of CO₂ is in the lower range of 30% to 40%. The CO₂ adsorption rates of the five adsorbents increased significantly as the theoretical loading increased to 30%, which reached 79.8%, 65.3%, 68.2%, 71.9%, and 73.7%, respectively. However, when the theoretical loading reaches 50%, the CO₂ adsorption rate...
shows a slight downward trend. This is because the loading of the active component on the surface of the support is mainly divided into three stages: unsaturated load, saturated load, and multilayer load. With the increase in K$_2$CO$_3$ loading from 10% to 30%, the load of the active component undergoes a process of an unsaturated state to saturation. When the loading increases from 30% to 50%, the load state is switched from a saturated load to a multi-layer load and, at this time, the active component has an overlapping multi-layer load phenomenon on the surface of the support. Hence, when the adsorbent undergoes a carbonation reaction, the outermost active component will first undergo a carbonation reaction to form KHCO$_3$. While KHCO$_3$ is a dense and smooth material and the formed product layer hinders the reaction of CO$_2$ with the active components of the inner layer, it results in a slight decrease in the adsorption rate of CO$_2$.

![Figure 2. CO$_2$ adsorption rate at different loading capacities.](image)

3.1.2. Carbonation Reaction Characteristics of Adsorbents under Different Adsorption Conditions

Carbonation reaction experiments of five kinds of adsorbents with the optimal theoretical loading (30%) were carried out under different CO$_2$ concentrations and reaction temperatures. When studying the effect of different CO$_2$ concentrations on the adsorption rate, the temperature was set to 70 °C. When studying the effect of different temperatures on the adsorption rate, the CO$_2$ concentration was set to 12.5% and the results are shown in Figures 3 and 4.

![Figure 3. CO$_2$ adsorption rate at different CO$_2$ concentrations.](image)
It can be concluded from Figure 3 that the CO₂ adsorption rate increases first and then decreases with the increase of CO₂ concentration and the optimal CO₂ concentration is 12.5%. This is because the difference between the CO₂ concentration on the surface of the adsorbent and the CO₂ concentration of the atmosphere is a driving force during the entire adsorption process. Hence, increasing the initial concentration of CO₂ can accelerate the adsorption rate, which promotes the CO₂ adsorption performance of the adsorbent. However, when the number and activity of the adsorbent sites on the adsorbents surface are certain, the concentration of CO₂ will also increase the adsorption capacity of the adsorbents, which leads to the decrease of the adsorption efficiency and the rate of the adsorbents. Therefore, the CO₂ adsorption performance of the adsorbent is inhibited. Among all the adsorbents, the CO₂ adsorption rate of K₂CO₃/AC is the largest and the degree of carbonation reaction of K₂CO₃/Al₂O₃ and K₂CO₃/5A is relatively close while the effect is poor.

It can be seen from Figure 4 that the optimal reaction temperature is 70 °C and the adsorption rates at 60 °C and 70 °C are relatively close. The CO₂ adsorption rate decreases significantly with the increase of temperature at the range of 70 to 90 °C. The adsorption of CO₂ on the supporting potassium-based adsorbent existed in both physical and chemical adsorption and the chemisorption was dominant. With the increase of the reaction temperature, the diffusion process of CO₂ in the surface of the adsorbent and the internal pores is accelerated, which is beneficial to the reaction of CO₂ with the adsorbent. Meanwhile higher temperature leads to easier breakage of chemical bonds and the lower energy barrier of the active component, which promotes chemical reaction. However, the reaction of K₂CO₃, CO₂, and H₂O to form KHCO₃ in the range of 120 to 200 °C is reversible. Hence, the activity of K₂CO₃ decreases and the reaction process tends to reverse when the temperature rises from 70 °C to 90 °C, which leads to the rapid decrease of the CO₂ adsorption rate.

In conclusion, the optimal theoretical loading of the adsorbent is 30% and the optimal adsorption reaction conditions include a CO₂ concentration of 12.5% and a reaction temperature of 70 °C. Moreover, among the active adsorbents prepared by five different supports, the K₂CO₃/AC adsorbent has the highest degree of carbonation reaction, which is followed by K₂CO₃/CFA, K₂CO₃/PFA, and K₂CO₃/5A adsorbents. K₂CO₃/Al₂O₃ has the worst activity.

3.2. Microscopic Characteristics

In this paper, the microscopic properties (pore structure and surface morphology) of the adsorbent before and after modification at the optimal theoretical loading were studied. Meanwhile, the composition and crystal structure of the adsorbent before and after carbonation reaction were studied.
3.2.1. Pore Structure

The pore structure parameters affecting the adsorption characteristics of the adsorbent mainly include specific surface area, specific pore volume, and pore size distribution. By taking the adsorbent before and after modification under optimal theoretical loading as the research object, \( \text{N}_2 \) adsorption/desorption experiment was carried out at a low temperature to study the pore structure of the adsorbent. The results are shown in Table 3. When studying the effect of the pore structure on the ability of the adsorbent to adsorb \( \text{CO}_2 \), the specific surface area per unit volume \( Z \) is introduced to characterize its pore richness \([25,26]\), which is represented by Formula (3) below.

\[
Z = \frac{S_0}{V_0}
\]  

(3)

where \( S_0 \) is the BET specific surface area of the adsorbent, \( \text{m}^2/\text{g} \). \( V_0 \) is the sum of the specific pore volumes of the adsorbent, \( \text{cm}^3/\text{g} \).

Furthermore, surface fractal dimension of the adsorbent can be selected as one of the evaluating parameter to characterize its pore structure. When the fractal dimension is 2, the surface of the object is smooth and regular. When the fractal dimension is close to 3, the surface structure becomes disordered and disordered. Its value can be obtained by the FHH (Frenkel, Halsey and Hill) equation \([27]\). Preifer et al. \([28]\) believe that the FHH theory applies to the adsorption and desorption processes in cryptopores (one to several ten nm). The fractal FHH equation is shown in Equation (4) and the fractal dimension of the internal pore surface of the particle can be determined by the \( \text{N}_2 \) adsorption isotherm. In the adsorption process, the adsorption interface is mainly affected by the Van der Waals Force in which the relationship between the constant \( S_N \) and the fractal dimension \( D_S \) is shown in Equation (5).

Thus, the fractal dimension can be calculated by simultaneous Equations (4) and (5).

\[
\frac{V}{V_m} = k \left( \ln \frac{P_0}{P} \right)^{S_N}
\]  

(4)

\[
S_N = D_S - 3
\]  

(5)

where \( V_m \) is the single layer saturated adsorption capacity, \( k \) is a constant, \( P \) is the pressure of the adsorbate, \( P_0 \) is the saturated vapor pressure of the adsorbate, \( S_N \) is a constant related to the adsorption mechanism and fractal dimension \( D \), and \( D_S \) is the fractal dimension.

From Table 3, the microstructure of \( \text{K}_2\text{CO}_3 \) is poor and its specific surface area and the cumulative pore volume are small. The adsorption of \( \text{CO}_2 \) by the adsorbent mainly depends on the chemical reaction. In addition, in all the adsorbents after loading, the BET specific surface area and the cumulative pore volume decreased greatly and the pore richness \( Z \) also showed a decreasing trend, which indicates that a large amount of \( \text{K}_2\text{CO}_3 \) adhered to the surface and pores of the support after loading.

Since the surface area and cumulative pore volume of AC are much larger than other supports, the active component is most loaded, which is beneficial to the carbonation reaction of the adsorbent after the loading modification. The specific surface area of the two kinds of fly ash decreased from 80.85 \( \text{m}^2/\text{g} \) and 99.70 \( \text{m}^2/\text{g} \) to 47.02 \( \text{m}^2/\text{g} \) and 73.17 \( \text{m}^2/\text{g} \) before and after loading and is only lower than AC and \( \text{K}_2\text{CO}_3/\text{AC} \). However, the cumulative pore volume of both before and after loading is small. When the 5A molecular sieve was used as the support, the specific surface area and cumulative pore volume of the adsorbent before and after loading decreased most clearly, which decreased by 80.94% and 67.88%, respectively. This is because, during the load process, the inside of the molecular sieve is plastically deformed due to surface tension and a large number of active components fill the pores, which results in deterioration of the microstructure. In addition, \( \text{Al}_2\text{O}_3 \) has a smooth and dense structure. Even though the pore structure is improved after loading \( \text{K}_2\text{CO}_3 \), the lifting effect is not significant.
Table 3. Pore structure parameters of adsorbents before and after loading with the optimal theoretical loading.

| Samples                | BET Specific Surface Area m²·g⁻¹ | Cumulative Pore Volume cm³·g⁻¹ | Fractal Dimension | Pore Richness Z | Relative Pore Volume % |
|------------------------|----------------------------------|-------------------------------|------------------|-----------------|------------------------|
|                        |                                  |                               |                  |                 | Micropore and Mesopore | Macropore              |

Combined with the results of CO$_2$ adsorption, it can be concluded that the type of support and the BET specific surface area of the adsorbent after loading modification determine the degree of the carbonation reaction while the cumulative pore volume and pore size distribution have less influence. This is because the process of adsorbing CO$_2$ by the active component K$_2$CO$_3$ on the support is a chemical reaction, which is dominant throughout the adsorption process. The larger the surface area, the more active sites on the surface of the support can adhere to K$_2$CO$_3$, which increases the adsorption of CO$_2$ by the adsorbent. When the cumulative pore volume is large, a large number of active components are attached to the pores. However, KHCO$_3$ formed by the reaction of external K$_2$CO$_3$ and CO$_2$ has a dense and less porous substance, which will hinder the diffusion of CO$_2$ into the pores and inhibit the continuous carbonation reaction. At the same time, it can be concluded that the fractal dimension and the CO$_2$ adsorption rate also have a proportional relationship and, with the increase of the fractal dimension, the surface morphology of the adsorbent gradually becomes irregular, which is beneficial for the sufficient contact of the active component with CO$_2$. This enhances the adsorption of CO$_2$ by the adsorbent.

3.2.2. Surface Morphology

In this paper, the support and corresponding modified adsorbent samples were observed by SEM and the surface morphology and microstructure of the supports and the adsorbents obtained under different modification conditions were obtained, which is shown in Figures 5–9.

As can be seen from Figure 5, the surface of the support AC has a rough surface and an irregular block structure. After the active component of K$_2$CO$_3$ is loaded, the original block structure is broken by the impregnation process and becomes a large number of irregular small particles. The surface and pores of the formed adsorbent are filled with a large amount of active components and the roughness is intensified. However, there are still significant gaps between the particles, which means the overall arrangement is loose.

![SEM image](image.png)

**Figure 5.** SEM image before and after AC loading. (a): The SEM image of AC; (b): The SEM image of K$_2$CO$_3$/AC.

Figure 6 shows the SEM results before and after loading the 5A molecular sieve. The molecular sieve particles before loading have a spherical structure with a rough surface and an abundant pore structure. The pores of the adsorbent after the loading are filled with a large amount of K$_2$CO$_3$, which confirmed the results of the previously mentioned reduction in a specific surface area and a cumulative pore volume. At the same time, it can be concluded that K$_2$CO$_3$ is loaded in a multi-layered manner in the pores. Therefore, after the surface-active component is completely reacted, the resistance of CO$_2$ into the internal channel increases and the carbonation reaction is hindered.
After loading, a large amount of the active components are deposited on the surface and the CO$_2$. However, the overall pore structure did not change significantly. Figure 6 shows an SEM image before and after 5A loading. (a): The SEM image of 5A; (b): The SEM image of K$_2$CO$_3$/5A.

Figure 7 shows an SEM image before and after loading Al$_2$O$_3$. Compared with other kinds of adsorbents, Al$_2$O$_3$ has a dense surface and a relatively regular layered structure. Although the surface structure is slightly improved after the impregnation, it is not significant and only a small amount of the active component is loaded on the surface.

Figure 8 shows an SEM image before and after the CFA loading. The surface morphology of the fly ash before loading is relatively rough and it is mainly composed of a dense porous structure. After loading, a large amount of the active components are deposited on the surface and the CO$_2$ can be sufficiently contacted to facilitate the carbonation reaction.

Figure 9 shows the SEM image before and after the PFA loading. The surface of the fly ash before loading contains a large number of round particles. The fly ash particles are fine and the shape is relatively simple. The particle diameter of the particles is different, the maximum is not more than 10 µm, and the diameter of most particles is 1–4 µm [29]. These particles are most likely aluminosilicate or fly ash balls. After the impregnation, the surface morphology changed greatly, the spherical particles disappeared, and the surface was loaded by the active components. However, the overall pore structure did not change significantly.
The main components before the PFA reaction are SiO$_2$, Al$_2$O$_3$, and CaSO$_4$. In addition, the miller index corresponding to the strong diffraction characteristic peaks of the main product KHCO$_3$ after the reaction are (1 0 4), (2 0 2), (2 1 1), and (4 0 0), (2 0 1), (−3 1 1). The main components before the CFA reaction are SiO$_2$, Al$_2$O$_3$, and CaSO$_4$ and the miller index corresponding to the strong diffraction characteristic peaks are (0 0 2) and (−1 2 1), respectively. The main products of the adsorbents with CFA and PFA as supports are KHCO$_3$.
and unreacted $\text{K}_2\text{CO}_3$ and the corresponding miller index are $(1\ 3\ -1)$, $(0\ 1\ 2)$, and $(-3\ 1\ 1)$, $(1\ 1\ 2)$, respectively.

3.3. Reaction and Adsorption Kinetics

The intrinsic reaction of the carbonation reaction of potassium-based adsorbent is the chemical reaction of K$_2$CO$_3$ particles with CO$_2$ and H$_2$O. The chemical reaction process of K$_2$CO$_3$ absorbing CO$_2$ is shown in Formula (6). It is a typical gas-solid non-catalytic reaction and the K$_2$CO$_3$ particles used in the experiment have a very small specific pore volume and are compact particles. Hence, the shrinking core model was used to describe its carbonation reaction mechanism [30].

$$K_2CO_3(s) + CO_2(g) + H_2O(g) = 2KHCO_3(s) \quad (6)$$

The carbonation reaction of adsorbent mainly includes three basic processes: gas film diffusion, surface adsorption, and intraparticle diffusion. Due to the rapid formation of the product layer with a larger specific volume than K$_2$CO$_3$ in the reaction process, the diffusion resistance of the mixed gas at the product layer is much greater than the diffusion resistance of the gas film. Hence, in the research process, the film diffusion process was ignored. Chemical reaction kinetic models and product layer diffusion kinetic models were used to study the reaction mechanism and main control forms. The chemical reaction control process is as shown in Formula (7) and the product layer diffusion control process is shown in Formula (8).

$$t = \frac{R_p^2}{6D_sC_A^2} \left[ 1 - \frac{1}{3}(1 - \eta_c)^{2/3} + 2(1 - \eta_c) \right] \quad (8)$$

where $k_s$ is the surface reaction control coefficient, min$^{-1}$.

where $t$ is the reaction time and $s$. $\rho_p$ is the molar density of the absorbent, mol/m$^3$. $R_p$ is the initial radius of the particle and $m$. $D_s$ is the diffusion coefficient of the gas in the product layer, m$^2$/s. $C_A^0$ is concentration of the reaction gas at time $t = 0$, mol/m$^3$. $n$ is the particle conversion rate, %.

In this paper, the shrinking core model was used to fit the carbonation reaction results of five adsorbents under different loading conditions at different reaction temperatures. The results are shown in Figure 11. The error between the relevant parameters obtained by fitting the equation and the experimental values is represented by the correlation coefficient $R^2$. The larger the value, the closer the description of the adsorption process is to the selected model. The correlation coefficients of all adsorbent samples obtained by fitting are close to 0.99. It can be concluded that the adsorption process of CO$_2$ on the adsorbent samples at different reaction temperatures is consistent with the nucleation kinetic model.

(a) Surface reaction control coefficient $k_s$  
(b) Internal diffusion coefficient $D_s$

Figure 11. Kinetic parameters of five adsorbents at different temperatures. (a): Surface reaction control coefficient $k_s$; (b): Internal diffusion coefficient $D_s$. 

Materials 2018, 11, 2424
From Figure 11, it is concluded that, as the reaction temperature increases, the surface reaction rate constant $k_s$ of the five adsorbents gradually increase. This is because the surface chemical reaction time is prolonged due to an increase in the reaction temperature and the carbonation pellet conversion rate is continuously increased. At the same time, the degree of reaction presents two stages. When the reaction temperature is lower than 70 $^\circ$C, the diffusion coefficient $D_e$ of the product layer gradually increases. This is because, during the adsorption process, the difference between the concentration of CO$_2$ and H$_2$O in the adsorbent surface and the adsorption atmosphere is the driving force in the whole adsorption process and the increase in temperature increases the adsorption rate and promotes the reaction, which accelerates the diffusion process of the reaction gas. In addition, when the reaction temperature is 70 $^\circ$C, the carbonation conversion rate is increased to the maximum value. When the reaction temperature is higher than 70 $^\circ$C, $D_e$ shows a decreasing trend. This is because, as the reaction proceeds, the nuclear radius of the unreacted particles of the adsorbent gradually decreases. In addition, since the active material in the adsorbent generates more products during the early carbonation reaction, the formed KHCO$_3$ product layer is more likely to wrap the surface of the adsorbent particles, which hinders the outward diffusion of the reactants in the adsorbent. At the same time, the diffusion of CO$_2$ and H$_2$O to the surface of unreacted particles is hindered and the internal diffusion resistance is remarkably enhanced.

In addition, since the carbonation reaction is jointly controlled by diffusion and a chemical reaction, the main control form of the reaction model is determined by the ratio $\rho (\rho = (1/A_2)/(1/A_1)) = (\rho_p R_P)/(\rho_p R_P^2) = \frac{6D_e}{k_s R_P}$ of the obtained chemical reaction rate constant $A_1$ and the diffusion rate constant $A_2$. When $\rho << 1$, the reaction is mainly controlled by the intrinsic chemical reaction. When $\rho >> 10$, the external mass diffusion is ignored and the reaction is controlled by the diffusion process through the product layer. When $\rho$ is between 1 and 10, the reaction is not only controlled by the intrinsic chemical reaction but also by the diffusion process through the product layer. The reaction is jointly controlled by both [31]. When the reaction temperatures are 50 $^\circ$C, 60 $^\circ$C, and 70 $^\circ$C, respectively, the $\rho$ values are 0.3569, 0.4623, and 0.8651, respectively, which indicates that the reaction is mainly controlled by the surface chemical reaction when the reaction temperature is lower than 70 $^\circ$C. When the temperatures are 80 $^\circ$C and 90 $^\circ$C, the $\rho$ values are 1.2963 and 1.3387, respectively, and the reaction is controlled by two processes, which verifies the above results.

In addition, in order to study the effect of temperature on the carbonation reaction process of the adsorbent, the Arrhenius equation was used. In addition, in the process of studying the influence of temperature on the carbonation reaction of adsorbent, the activation energy was obtained by the Arrhenius equation, which is shown in Formula (9). During the calculation, the logarithm of the two sides of the Arrhenius equation is obtained to obtain Equation (10). By using 1/T as the abscissa and ln($k_s$) as the ordinate for linear fitting, the adsorption activation energy during the adsorption reaction can be obtained. The corresponding fitting results are shown in Figure 12.

$$k_s = A_{r1} \exp(-E_{a1}/RT) \quad (9)$$

where T is the reaction temperature, K, $A_{r1}$ is the pre-exponential factor of the surface reaction process, min$^{-1}$. $E_{a1}$ is the activation energy of the surface reaction process, kJ/mol. R is the gas constant, 8.314 J/(mol·K).

$$\ln(k_s) = -E_{a1}/RT + C \quad (10)$$

where C is a constant.
The activation energies of $K_2CO_3/AC$, $K_2CO_3/PFA$, $K_2CO_3/CFA$, $K_2CO_3/5A$, and $K_2CO_3/Al_2O_3$ are $29.82$ kJ/mol, $32.91$ kJ/mol, $36.02$ kJ/mol, $40.57$ kJ/mol, and $46.21$ kJ/mol, respectively. Activation energy refers to the energy required for a molecule to change from a normal state to an active state in which a chemical reaction is likely to occur, which reflects the difficult degree of a chemical reaction. Among the five adsorbents, $K_2CO_3/AC$ has the lowest activation energy and the carbonation reaction is the easiest to carry out, so the reaction rate and carbonation degree are the largest. Similarly, the activation energy of the $K_2CO_3/Al_2O_3$ adsorbent is the highest and the carbonation reaction is difficult, which results in the lowest degree of carbonation of the adsorbent.

It can be seen from the above information that the adsorption process of $CO_2$ by adsorbents mainly includes three basic processes: external mass transfer, surface adsorption, and intraparticle diffusion. Hence, the pseudo-first order kinetic model, the pseudo-second order kinetic model, the intra-particle diffusion model, and the Elovich model are used to study the decarburization mechanism of different kinds of adsorbents and determine the rate-determining step in the adsorption process. The pseudo-first order kinetic model and the intra-particle diffusion model mainly study the physical adsorption process while the pseudo-second order kinetic model and the Elovich model are mainly used to study chemisorption. Among them, pseudo-first order kinetics mainly studies the external mass transfer process, which is shown in Formula (11). The pseudo-second order kinetic model is based on the Langmuir adsorption isotherm equation to study the formation of chemical bonds to verify that the adsorption process is dominated by chemisorption, which is shown in Formula (12). The intra-particle diffusion model is derived from the mass balance equation, which mainly studies the internal diffusion process of the pores during solid adsorption, as shown in Equation (13). The Elovich model is based on the Temkin adsorption isotherm equation and mainly describes the chemisorption process. It is similar to the pseudo-second order and the fitting results of the two models can be used to verify the accuracy of each other, which is shown in Equation (14).

\[
q = q_e \left(1 - e^{-kt_1}\right) 
\]  
(11)

where $q$ is the adsorption amount of the adsorbent per unit mass at time $t$, g/g. $q_e$ is the adsorption amount of the adsorbent per unit mass in equilibrium, g/g. $t$ is the adsorption time, min. $k_1$ is the pseudo-first order rate constant, min$^{-1}$.

\[
q = \left(\frac{q_e^2k_2t}{1 + q_ek_2t}\right) 
\]  
(12)

where $k_2$ is the pseudo-second order rate constant, ng/(g·min).

\[
q = k_{id}t^{1/2} + C 
\]  
(13)
where $k_{id}$ is the intra-particle diffusion rate constant, $g/(g \cdot \text{min}^{1/2})$. $C$ is the constant related to the thickness of the boundary layer, $g/g$. It decreases with the increase of heterogeneity and hydrophilic groups of the adsorbent surface. The larger the value, the greater the influence of the boundary layer on the adsorption.

$$q = (1/\beta) \ln(t + t_0) - (1/\beta) \ln(t_0)$$

(14)

where $\alpha$ is the initial adsorption rate, $g/(g \cdot \text{min}^{1/2})$. $\beta$ is a constant related to the surface coverage and activation energy, $ng/g$. $t_0 = 1/(\alpha \cdot \beta)$.

The four adsorption kinetic models were used to calculate and fit the adsorbent carbon adsorption experimental data. The results are shown in Table 4. The correlation coefficients $R^2$ of different adsorbents are all close to 0.99. It can be concluded that the adsorption process of CO$_2$ by different kinds of adsorbents is consistent with these four kinetic models. The adsorption process is affected by both physical adsorption and chemical adsorption. The adsorption of CO$_2$ is not a single monolayer layer adsorption, but it is related to the adsorption site of the adsorbent. Moreover, through the predicted equilibrium adsorption amount $q_e$ in the pseudo-first order and pseudo-second order kinetic models, it can be concluded that the adsorption process of CO$_2$ by the five adsorbents do not reach a saturation state within 60 min and $q_e$ has a positive correlation with its actual adsorption amount, which verifies the correctness of the fitting results. The fitting coefficient of the pseudo-first order kinetic model of K$_2$CO$_3$/Al$_2$O$_3$-30% sample is higher than that of the pseudo-second order kinetic model, which indicates that the rate-determining step is mainly a physical adsorption process, but its pseudo-first order and pseudo-second order rate constants are low, as mentioned above. This is mainly due to the poor surface pore structure and the low content of active substances. In addition, the rate-determining step of the other adsorbents is mainly chemical adsorption.
Table 4. Fitting parameters of different sorbents.

| $\text{K}_2\text{CO}_3$/$\text{AC}$ | 0.9995  | 7.39 $\times$ 10$^{-4}$ | 6404 | 0.9999  | 6.46 $\times$ 10$^{-7}$ | 10199 | 0.9948  | 36.4391 | −957 | 0.9991 | 0.8879 | 2.54 $\times$ 10$^{-4}$ |
In addition, the intra-particle diffusion model was used to fit the cumulative CO₂ adsorption amount per unit mass of different adsorbents and the results are shown in Figure 13. With the increase of adsorption time, the overall trend of $k_{id}$ is increasing and the actual adsorption rate of CO₂ decreases with the increase of adsorption time, the contradiction between the CO₂ adsorption rate, and the internal diffusion rate indicates that there is surface adsorption during CO₂ adsorption. Hence, the CO₂ adsorption process can be divided into two stages: surface adsorption stage and internal diffusion adsorption stage. In the initial adsorption stage, the surface adsorption is the main form of adsorption because a large number of adsorption active sites exist on the surface of the adsorbent. Therefore, the surface adsorption rate is faster while the internal diffusion rate is smaller, which indicates that, in this stage, intra-particle diffusion does not play a leading role. When the active sites of the surface are occupied, the second stage of adsorption is carried out and diffusion adsorption occurs in the pore. At this time, the micropores and mesopores provide the adsorption active sites of CO₂. Therefore, the adsorption rate is continuously decreased and the internal diffusion rate is increased. Moreover, the fitting curves of all intra-particle diffusion models have not passed through the origin, which is quite different from the experimental results. This indicates that the internal diffusion model cannot describe the adsorption process of CO₂ on the adsorbent surface. The internal diffusion process is not the rate-determining step. The correlation coefficients obtained by the internal diffusion model fitting are small and significantly lower than the correlation coefficients obtained by fitting the pseudo-first order kinetic model, which indicates that the external mass transfer process is the rate-determining step for the adsorption of CO₂ on the surface of the adsorbent relative to the internal diffusion process. In addition, although the fitting curves of the pseudo-second order model can be well matched with the experimental results, the correlation coefficients is slightly lower than the correlation coefficients obtained by the pseudo-first order model. In addition, the equilibrium CO₂ adsorption amount obtained by fitting the pseudo-first order kinetic model is closer to the experimental results. Hence, the conclusion that the external mass transfer is the rate-determining step of CO₂ adsorption on the adsorbent surface is further verified and the adsorption of CO₂ at the active sites also plays a more important role. In addition, the fitting curves of the Elovich dynamic model are also in good agreement with the experimental results, which verifies the existence of the chemisorption process at the active site. The Elovich equation is based on the Temkin adsorption isotherm equation. Hence, it can be considered that the adsorption of CO₂ on the adsorbent surface also follows the Temkin adsorption isotherm equation.

![Figure 13. Fitting of intra-particle diffusion kinetic equation.](image)

### 3.4. Study on the Effect of Flue Gas Composition on the Failure Characteristics of Adsorbents

In this paper, the adsorption/regeneration cycles of K₂CO₃/AC, K₂CO₃/Al₂O₃, K₂CO₃/5A, K₂CO₃/CFA, and K₂CO₃/PFA adsorbents were carried out and the degree of failure was characterized by the failure rate $\eta_f$, which is shown in Formula (15). In addition, in practical application research,
it is found that when \( \eta_F > 20\% \), it indicates that the adsorbent has insufficient ability to capture CO\(_2\). Hence, in the study of failure characteristics in this paper, 20\% is selected as the critical value of adsorbent failure.

\[
\eta_F = (1 - \frac{\eta_n}{\eta_0}) \times 100\% 
\]  

(15)

In the formula, \( \eta_n \) is the adsorption rate of CO\(_2\) after \( n \) times of cycle, \%. \( \eta_0 \) is the adsorption rate of CO\(_2\) in the first carbonation reaction, \%.

Figure 14 shows the variation of the failure rate of different adsorbents with the number of cycles. It can be concluded that the failure characteristics of the five adsorbents are basically the same. The failure rate of all adsorbents in the first 10 cycles increases slowly, but, as the number of cycle increases, the failure rate increases. The K\(_2\)CO\(_3\)/AC adsorbent has the highest number of cycles when the failure rate reaches more than 20\%. The failure rate was only 21.8\% until the 23rd cycle. In contrast, K\(_2\)CO\(_3\)/Al\(_2\)O\(_3\) has the worst cycle failure characteristic and the failure rate after 14 cycles is as high as 21.2\%.

In addition, in the study of the influence of flue gas composition on the failure characteristics of adsorbents, it is found that, in the presence of SO\(_2\), K\(_2\)CO\(_3\) and SO\(_2\) will react similar to that in Formula (16) and Formula (17). HCl also reacts with K\(_2\)CO\(_3\) to render the adsorbent failure, as shown in Formula (18). NO is stable at low temperatures and does not participate in the reaction with the active components. The five types of supports cannot react with the three acid gases under low temperature and normal pressure. Therefore, the main factors causing the difference in the failure rate are the adsorbent loading and its own CO\(_2\) adsorption rate.

\[
K_2CO_3 + SO_2 \rightarrow K_2SO_3 + CO_2 
\]  

(16)

\[
3K_2CO_3 + 2.5H_2O + SO_2 \rightarrow K_4H_2(CO_3)_3 \cdot 1.5H_2O + K_2SO_3 
\]  

(17)

\[
K_2CO_3 + 2HCl \rightarrow 2KCl + H_2CO_3 
\]  

(18)

4. Conclusions

(1) The actual loading of K\(_2\)CO\(_3\)/AC adsorbent is the largest and the adsorption performance of CO\(_2\) is the best, which is followed by the K\(_2\)CO\(_3\)/PFA, the K\(_2\)CO\(_3\)/CFA, and the K\(_2\)CO\(_3\)/5A adsorbent and the load modification of K\(_2\)CO\(_3\)/Al\(_2\)O\(_3\) adsorbent is poor while the CO\(_2\) adsorption rate is the lowest.

(2) As the theoretical loading of the five adsorbents increases from 10\% to 50\%, the CO\(_2\) adsorption rate first increases and then decreases. The best theoretical loading is 30\% and the reaction temperature of 70 °C and the concentration of 12.5\% CO\(_2\) are the best reaction conditions.
(3) The microstructure of the adsorbents are different after modification of different supports and the cumulative pore volume plays a more important role in the adsorption process than the specific surface area. Among them, K₂CO₃ reacts with Al₂O₃ to produce KAl(CO₃)₂(OH)₂ and the support and active component compete for adsorption, which reduces the chemisorption of CO₂.

(4) With the increase of the reaction temperature, the internal diffusion resistance is significantly enhanced. K₂CO₃/AC has the lowest activation energy and the carbonation reaction is the easiest. The adsorption process of CO₂ by the adsorbent is affected by both physical adsorption and chemical adsorption and CO₂ adsorption is related to the adsorption sites of the adsorbent rather than a single monolayer adsorption.

(5) In the simulated flue gas, SO₂ and HCl react with K₂CO₃ to produce new substances, which causes the adsorbent to gradually fail and K₂CO₃/AC has the best cycle failure performance.

Author Contributions: Conceptualization, B.-g.F. Funding acquisition, B.-g.F. Investigation, L.J., Y.-L.W., R.Z. and Y.J. Project administration, L.J. and Y.J. Resources, X.-s.M. and Y.-y.L. Writing—review & editing, L.J.

Funding: The authors acknowledge the financial support for this work provided by the National Natural Science Foundation of China (No. U1510129), the National Natural Science Foundation of China (No. U1510135), the Science and technology major projects of Shanxi Province (No. MD2015-04).

Conflicts of Interest: The authors declare no conflict of interest. The funders had no role in the design of the study, in the collection, analyses, or interpretation of data, in the writing of the manuscript, or in the decision to publish the results.
