Background. Complicated intra-abdominal infections (cIAIs) result in significant morbidity, mortality, and cost. Carbapenem-resistant sepsis has increased dramatically in the last decade, resulting in infections that are difficult to treat and associated with high mortality rates. To prevent further antibacterial resistance, it is necessary to use carbapenem selectively. The objective of this study was to compare the effectiveness and safety of carbapenems vs alternative β-lactam monotherapy or combination therapy for the treatment of cIAIs.

Methods. The PubMed, Embase, Medline (via Ovid SP), and Cochrane library databases were systematically searched. We included randomized controlled trials (RCTs) comparing carbapenems vs alternative β-lactam monotherapy or combination therapy for the treatment of cIAIs.

Results. Twenty-two studies involving 7720 participants were included in the analysis. There were no differences in clinical treatment success (odds ratio [OR], 0.86; 95% confidence interval [CI], 0.71–1.05; I² = 35%), microbiological treatment success (OR, 0.88; 95% CI, 0.71–1.09; I² = 25%), adverse events (OR, 0.98; 95% CI, 0.87–1.09; I² = 17%), or mortality (OR, 0.96; 95% CI, 0.68–1.35; I² = 7%). Patients treated with imipenem were more likely to experience clinical or microbiological failure than those treated with alternative β-lactam monotherapy or combination therapy.

Conclusions. No differences in clinical outcomes were observed between carbapenem and noncarbapenem β-lactams in cIAIs. Patients treated with imipenem were more likely to experience clinical or microbiological failure than those treated with alternative β-lactam monotherapy or combination therapy.

Keywords. carbapenem; β-lactam; complicated intra-abdominal infections; meta-analysis; systematic review.

Complicated intra-abdominal infections (cIAIs) are common in clinical practice and a frequent reason for hospitalization. They are often caused by a mixture of aerobic and anaerobic bacteria and have a high likelihood of developing into sepsis or septic shock [1]. Intra-abdominal infections consist of a wide spectrum of diseases, ranging from simple peritonitis or acute appendicitis to feculent diverticulitis or perforated appendicitis and other penetrating intra-abdominal injuries [2]. Common microorganisms isolated from intra-abdominal samples are gram-negative pathogens, mainly associated with normal enteric flora such as Escherichia coli, Klebsiella pneumoniae, and Pseudomonas aeruginosa [2, 3]. Patients with hospital-acquired infections have a higher prevalence of multidrug-resistant strains such as extended-spectrum β-lactam–producing Enterobacteriaceae, carbapenem-resistant Enterobacteriaceae, and glycopeptide-resistant Enterococcus spp. [4–6].

The outcome of cIAIs, which are intra-abdominal infections extending beyond the wall of a hollow organ, depends on timely diagnosis and treatment including operative interventions and appropriate antimicrobial therapy [7]. The timing of antibiotic treatment also affects mortality, especially delays in antibiotic administration upon arrival at the hospital [8–10]. The antimicrobial therapies recommended for cIAIs in the guidelines by the Expert Panel of the Surgical Infection Society and the Infectious Diseases Society of America include carbapenem or other β-lactams as monotherapy or combination therapy [3].

Carbapenems have been proven to have a wider spectrum against bacteria in comparison with β-lactam antimicrobials, and therefore are often reserved for severe, complicated, and multidrug-resistant infections [11], and carbapenems also have a low propensity for the selection of mutants that are highly resistant...
Studies meeting the following criteria were included: (i) population: patients with cIAIs; (ii) intervention: cIAI patients treated with carbapenems; (iii) comparison: cIAI patients treated with β-lactam monotherapy or combination therapy; (iv) outcome: primary outcomes: clinical treatment success and microbiological treatment success; secondary outcomes: all adverse events, mortality; (vi) design: randomized controlled trials (RCTs).

Exclusion Criteria
The exclusion criteria were (i) reviews, nonclinical studies, and case observations; (ii) not RCTs; (iii) reduplicated studies; (iv) improper outcome measures; (v) meta-analyses, case reports, and editorials.

Selection of Studies and Data Extraction
Comprehensive search of databases was performed by 2 researchers (Li and Chen), who deleted duplicate records, screened the titles and abstracts for relevance, and identified each article as excluded or requiring further assessment. We reviewed the full-text articles designated for inclusion and manually checked the references of the retrieved articles and previous reviews to identify additional eligible studies. Discrepancies were resolved by consensus. The following data were extracted from each study: study design, first author, year of publication, number of patients, age category (adult or child), interventions, comparisons, and outcomes.

Risk of Bias Assessment
Three reviewers (Li, Chen, and Jiang) independently evaluated the methodological quality of identified studies. The Risk of Bias Tool from the Cochrane Handbook for Systematic Reviews of Interventions, version 5.3.0, was used to assess methodological quality [17, 18]. In terms of the assessment criteria, each trial was rated and assigned to 1 of the 3 following levels of risk of bias: low: if all quality criteria were adequately met; unclear: if 1 or more of the quality criteria was only partially met or was unclear, the trial was deemed to have a moderate level of risk of bias; or high: if 1 or more of the criteria were not met, or not included, the trial was deemed to have a high level of risk of bias [18, 19].

Data Analysis
Data were analyzed using the Review Manager 5.3.0. statistical package (Cochrane Collaboration Software). Dichotomous outcomes were expressed as odds ratios (ORs) with 95% confidence intervals (CIs). A test of heterogeneity was conducted with the Q test and Q statistic, which is distributed as a χ² variate under the assumption of homogeneity of effect sizes. An I² value >50% or P value <.05 was assumed to indicate significant heterogeneity [20]. Publication/reporting biases were visually assessed using funnel plots. If there was no observed heterogeneity, the fixed-effect model was chosen; otherwise a random-effects model was used [21].

Sensitivity analysis used a separate evaluation of studies with low risk of selection bias for concealment or double-blind design studies. Subgroup analyses were performed for the primary
outcome, and based on the following: (i) stratifying the studies based on specific carbapenems such as ertapenem, imipenem/cilastatin, or meropenem vs β-lactam monotherapy or combination therapy; (ii) a subgroup of trials published since 2000 to reflect modern medicine; (iii) based on a clinical modified intent-to-treat (c-mITT) population or a microbiological modified intent-to-treat (m-mITT) population; (iv) based on specific antimicrobials, source of infection, and isolated pathogens.

RESULTS

Study Identification and Selection
A total of 1299 records were retrieved from the initial database search. After removing 390 duplicate articles, 909 records were eligible. Based on the inclusion and exclusion criteria, 790 articles were excluded after a simple reading of the titles and abstracts of the articles. The remaining 119 full-text articles were assessed for eligibility. Furthermore, studies with a design that was not relevant, non-RCTs, meta-analyses, studies with no outcomes, and those with mixed infections reported were excluded. Finally, a total of 22 RCT studies [22–43] were included in the meta-analysis. The selection process was conducted according to the PRISMA guidelines and is depicted in Figure 1. Among the 22 RCTs, 14 studies evaluated carbapenems compared with β-lactam combination therapy [22, 23, 25, 26, 29–34, 36, 38, 40, 42], β-lactam in combination with metronidazole was evaluated in 13 studies, and 1 study evaluated aztreonam combined with lindamycin [26]. Eight studies evaluated carbapenems compared with β-lactam monotherapy [24, 25, 27, 28, 35, 37, 41, 43], 7 studies evaluated piperacillin/tazobactam, and 1 trial evaluated ticarcillin/clavulanate [43]. As for carbapenems, ertapenem, imipenem/cilastatin, and meropenem were evaluated in 7, 8, and 7 studies, respectively.

Study Characteristics
The basic characteristics of the included studies are listed in Table 1, and the definition of clinical/microbiological and timing of evaluation are shown in Supplementary Table 1. Twenty-two RCTs studies involving 7720 participants were included in the analysis. These studies were published from 1987 to 2017. The number of participants in the studies ranged from 56 to 1066.

Risk of Bias Assessment
The Cochrane Risk of Bias Tool was used to assess the quality of our study [17]. The outcomes of the risk of bias are summarized in Supplementary Figure 1A and Supplementary Figure 1B. Almost half of the included RCTs were assessed to be of a high methodological quality. Twelve studies [23, 29, 32–36, 38–42] had low risk for sequence generation and allocation concealment. Nine trials [22, 24, 25, 27, 28, 30, 31, 37, 43] were performed using an open-label model, with a high risk for performance bias and detection bias, and 1 RCT [26] did not mention whether blinding procedures were used.

As for attrition bias, all trials had a low risk of bias for selective outcome reporting, and all but 2 had a low risk of bias for incomplete outcome data reporting [22, 30].

In addition to other biases, 2 studies, Huizinga et al. [30] and Kempf et al. [31], were reported to have an unbalanced Acute Physiologic Assessment and Chronic Health Evaluation (APACHE) II score, with higher scores in the carbapenem group.

Clinical Treatment Success
Twenty-one studies including a total of 5088 patients provided data on clinical treatment success. Compared with carbapenems, β-lactams showed no significant difference in terms of clinical success (OR, 0.86; 95% CI, 0.71–1.05; P = .13; I² = 35%) (Figure 2). Furthermore, in subgroup analysis by type of carbapenem compared with β-lactam monotherapy or combination therapy, we found that patients treated with imipenem/cilastain were more likely to experience clinical failure vs alternative β-lactam, regardless of whether it was monotherapy or combination therapy (OR, 0.38; 95% CI, 0.21–0.67; P < .01; I² = 46%; OR, 0.66; 95% CI, 0.46–0.96; P = .03; I² = 26%, respectively) (Figure 2). No clinical treatment success difference was found between ertapenem with β-lactam monotherapy or combination therapy (OR, 0.99; 95% CI, 0.58–1.68; P = .96; I² = 0%; OR, 1.07; 95% CI, 0.53–2.18; P = .85; I² = 0%, respectively) (Figure 2). Similar results were observed in meropenem vs β-lactam combination therapy (OR, 1.25; 95% CI, 0.91–1.71; P = .17; I² = 0%) (Figure 2).

In a subgroup analysis including studies since 2000, there was no significant difference between carbapenems and alternative β-lactam (OR, 1.01; 95% CI, 0.79–1.29; P = .94; I² = 0%) (Supplementary Figure 2). Similar results were observed in a subgroup analysis including studies only for a c-mITT population (OR, 1.11; 95% CI, 0.95–1.29; P = .19; I² = 34%) (Supplementary Figure 3).

A sensitivity analysis using trials with low risk of selection bias due to concealment is presented in Supplementary Figure 4; it showed similar results (OR, 0.92; 95% CI, 0.71–1.18; P = .50; I² = 0%). Similar results of trials with a double-blind design are shown in Supplementary Figure 5 (OR, 0.90; 95% CI, 0.70–1.15; P = .38; I² = 0%).

Microbiological Treatment Success
Microbiological treatment success was evaluated by 3708 investigators in the 19 trials, although explicit definitions of microbiological treatment success were only reported for some trials (Supplementary Table 1). Microbiological treatment success occurred in 1717/1936 patients (88.69%) treated with a carbapenem and 1596/1772 (90.07%) treated with an alternative β-lactam monotherapy or combination therapy. There were no significant differences in microbiological treatment success between carbapenems and alternative β-lactam monotherapy or combination therapy (OR, 0.88; 95% CI, 0.71–1.09;
In a subgroup analysis by type of carbapenem compared with β-lactam monotherapy or combination therapy, similar results were shown, that patients treated with imipenem/cilastain were more likely to experience microbiological failure vs those treated with alternative β-lactam, regardless of whether it was monotherapy or combination therapy (OR, 0.33; 95% CI, 0.15–0.73; \( P = .006; I^2 = 0\%\); OR, 0.55; 95% CI, 0.35–0.85; \( P = .007; I^2 = 0\%\), respectively) (Figure 3). No microbiological treatment success difference was found between ertapenem with β-lactam monotherapy vs combination therapy (OR, 1.12; 95% CI, 0.79–1.58; \( P = .54; I^2 = 28\%\); OR, 1.51; 95% CI, 0.64–3.59; \( P = .35; I^2 = 0\%\), respectively) (Figure 3). Similar results were observed in meropenem vs β-lactam combination therapy (OR, 1.28; 95% CI, 0.79–2.08; \( P = .31; I^2 = 0\%\)) (Figure 3).

In a subgroup analysis including studies since 2000, there was no significant difference between carbapenems and alternative β-lactam (OR, 1.10; 95% CI, 0.86–1.42; \( P = .44; I^2 = 0\%\)) (Supplementary Figure 6). However, in a subgroup analysis including an m-mITT population, patients treated with carbapenems were more likely to experience microbiological treatment success vs alternative β-lactam monotherapy or combination therapy (OR, 1.50; 95% CI, 1.20–1.87; \( P = .0003; I^2 = 0\%\)) (Figure 4).

In a subgroup analysis including patients with infection caused by *E. coli*, *K. pneumoniae*, *P. aeruginosa*, *Enterobacter* spp., and *Enterococcus* spp., no significant difference was observed between carbapenems and alternative β-lactam monotherapy or combination therapy (Table 2; Supplementary Figure 7).

A sensitivity analysis using trials with low risk of selection bias due to concealment is presented in Supplementary Figure 8; it showed similar results (OR, 0.96; 95% CI, 0.73–1.25; \( P = .74; I^2 = 34\%\)). Similar results of trials with a double-blind design are shown in Supplementary Figure 9 (OR, 1.00; 95% CI, 0.78–1.29; \( P = .98; I^2 = 16\%\)).

**Adverse Events**

Twenty studies included a total of 6812 patients who had experienced adverse events (AEs). This analysis revealed no significant difference between carbapenems and alternative β-lactam monotherapy or combination therapy (OR, 0.98;

Abbreviations: A, adult; APACHE, Acute Physiology and Chronic Health Evaluation; B, both adult and child; C, child; cIAI, complicated intra-abdominal infection; NR, not reported; RCT, randomized controlled trial; TOC, test of cure.
In the present study, we systematically reviewed all published RCTs comparing carbapenem-based regimens vs alternative β-lactam-based regimens of monotherapy or combination therapy for the treatment of patients with cIAIs. The results of the primary outcomes showed no difference in the clinical and microbiological treatment success or in the risk of AEs and mortality among cIAI patients treated with either a carbapenem or a noncarbapenem β-lactam agent monotherapy or combination therapy. In general, subgroup analyses of cIAIs did not reveal an advantage for using...
Few meta-analysis studies have compared the efficacy and safety of combined therapy with carbapenems vs alternative β-lactam single or combination therapy for the treatment of cIAIs in recent years. A similar meta-analysis conducted in 2016 investigated the efficacy of metronidazole combination therapies and carbapenem and suggested that combined therapy with metronidazole can be an effective and safe treatment for either of the subgroups tested, including type of carbapenem, year of publication, modified ITT population, and type of pathogen. Exceptions were microbiological treatment success in the subpopulation of ITT, which was significantly more likely with carbapenems. In addition, for the outcomes of clinical and microbiological success, significantly lower success rates were noted with imipenem as the comparator for carbapenem.
### Table 2. Subgroup Analysis of Per-Pathogen Microbiological Treatment Success

| Study or subgroup | Carbapenem | β-Lactam | Odds ratio M-H, Fixed, 95% CI | Odds ratio M-H, Fixed, 95% CI |

option for cIAI, similar to carbapenems [44]. However, this study did not include β-lactam monotherapy and included only 8 trials comparing β-lactams vs carbapenems.

Antimicrobial therapy for cIAIs is prescribed empirically. The Surgical Infection Society, the Infectious Diseases Society of America, and the World Society of Emergency Surgery published guidelines on this issue, suggesting that fluoroquinolones and β-lactams alone or, when needed, in combination with metronidazole are equally effective [45]. The choice of therapy is physician-oriented and is based on the local bacterial epidemiology, the infection site, acquisition (eg, community-acquired, health care–associated, or hospital-acquired), and risk for treatment failure and death [46].

In 2014, the intravenous formulation of metronidazole was approved in Japan, long after the oral formulation was first approved in 1961 [44]. When evaluating carbapenems compared with β-lactam combination therapy, our study showed results similar to those published in previous study, and the findings of this analysis confirm the majority of the recommendations regarding antibiotic treatment for patients with cIAIs. On the other hand, our analysis also focused on RCTs, which is the only design that allows the testing of interventions with β-lactam monotherapy for patients with cIAIs. Similar results were observed with carbapenems compared with β-lactam monotherapy. Piperacillin/tazobactam is one of the currently recommended agents for empiric treatment of cIAI in lower-risk patients, and the current recommendation is to reserve this agent for higher-risk patients because of its broad-spectrum antimicrobial activity [45].

An increased risk of failure of clinical and microbiological treatment has been observed in patients treated with imipenem/cilastatin compared with β-lactam monotherapy or combination therapy. Most of the included studies that evaluated imipenem/cilastatin were published before 2000 and might not reflect modern medicine. These features are increasingly crucial to guide therapy and outline optimal evidence-based management recommendations. On the other hand, ertapenem and meropenem showed similar clinical and microbiological treatment success compared with β-lactam monotherapy or combination therapy. However, carbapenem-resistant Enterobacteriaceae including Klebsiella spp. and E. coli, in particular, has increased dramatically in the last decade. There are limited therapeutic options available for infections caused by carbapenem-resistant Enterobacteriaceae; therefore, these infections are difficult to treat and associated with high mortality rates [47], and there is a critical need to use existing agents carefully to prevent the emergence of drug-resistant bacteria.

This meta-analysis has certain limitations. First, the pharmacokinetic data of antibacterial agents used in the included studies were not reported, which restricts the evaluation of the adequacy of the administered doses, which might lead to a bias in the pooled effect. Second, intra-abdominal infections

**Carbapenems vs β-Lactam for Complicated Intra-abdominal Infections • OFID • 9**
encompass a wide range of infections with different bacterial patterns that depend on the source, such as gastroduodenal vs appendix vs colon, and it is possible that certain antimicrobials perform better for upper or lower gastrointestinal infections and worse for other infections, but cumulatively they appear equal. In addition, variables including age, sex, underlying disease, nutritional status, and assessment time point of patients were also potential bias-inducing factors. Third, source control is of paramount importance in patients with cIAIs and is difficult to standardize [48]; this study used the primary outcome of clinical and microbiological treatment success to reduce the likelihood of misclassification bias, but the identified studies used different definitions of “clinical and microbiological treatment success.” Fourth, the enrolled patients were not stratified by severity of illness, and mortality was 2%, which suggests that the most severely ill patients were under-represented in the analyzed trials [49] and extrapolation of our findings in this population should be performed with caution. Last but not least, about 40% of included trials were open label, which may lead to increased risk of performance and detection bias, especially in subjective outcomes.

CONCLUSIONS

In conclusion, the current meta-analysis revealed that β-lactam monotherapy or combination therapy can be an effective and safe treatment option for cIAIs, similar to carbapenem. Ertapenem and meropenem appear to be similarly effective to other β-lactam monotherapy or combination therapy for a variety of pathogens that cause cIAIs. However, increased risk of failure of clinical and microbiological treatment was observed in patients treated with imipenem/cilastatin compared with β-lactam monotherapy or combination therapy. The results were consistent when differences in therapy drug type and potential cofounders of the identified studies were considered. In addition, empiric antimicrobial treatment of patients with cIAIs should be selected in light of the local bacterial epidemiology and patterns of resistance. Further research may focus on subgroups such as patients with health-care-associated cIAIs and critically ill patients; clinical outcomes should ideally be stratified by infection site, such as appendicitis.

Supplementary Data

Supplementary materials are available at Open Forum Infectious Diseases online. Consisting of data provided by the authors to benefit the reader, the posted materials are not copyedited and are the sole responsibility of the authors, so questions or comments should be addressed to the corresponding author.
