ABSTRACT

Background and Objectives: Enzootic abortion of ewes (EAE) is caused by infection of sheep and goats by Chlamydia abortus bacterium. Chlamydial abortion in bovine could occur by Chlamydia abortus, Chlamydia psittaci and Chlamydia pecorum. C. psittaci is the causative agent of psittacosis or ornithosis disease in humans and birds. It also causes acute pneumonia in cattle and sheep. The present study aimed at surveying the role of chlamydial agents in ruminants abortion.

Materials and Methods: A total of 117 aborted material samples (Cotyledon, liver, spleen, and abomasal contents of fetus) from 9 cattle and 100 sheep in Shahr-e-Kord and 8 sheep from Bagh-e-Malek were collected from different herds with abortion history during the lambing periods from 2014 to 2016. After DNA extraction, the samples were tested by species-specific PCR to detect C. abortus, C. pecorum and C. psittaci.

Results: Out of 117 clinical sample (108 sheep and 9 cattle), chlamydial infection was detected in 66 (56.41%) samples by Chlamydiales order-specific primers. A total of 24 (36.36%) and 24 (36.36%) samples indicated positive forms of C. abortus and C. psittaci infections, respectively. Only 1 (1.5%) C. pecorum was identified from cattle using nested PCR during this study. Among 66 Chlamydiales- positive samples, 20 (30.30%) samples with coinfection of C. abortus and C. psittaci were detected, however, infection of 3 species was not detected in the samples.

Conclusion: Because of the high percentage of chlamydial infection in these regions and probability of coinfection, conducting epidemiological studies on the role of different animals is highly recommended.

Keywords: Abortion, Chlamydia, Goat, PCR, Sheep

INTRODUCTION

The family Chlamydiaceae contains obligate intracellular Gram-negative bacteria, with 11 confirmed species (C. trachomatis, C. suis, C. psittaci, C. pneumoniae, C. pecorum, C. muridarum, C. gallinacea, C. felis, C. caviae, C. avium and C. abortus) and can-
Animals that have been infected before pregnancy usually occurs in the last 2 to 3 weeks of pregnancy. Abortion is the reason for abortion and the birth of weak lambs in ewes (EAE) (5). This is the most common infectious abortion in sheep-rearing countries of the world. Abortion percentage in affected flocks is low in the first year and then reaches 30% and 10% in the second and third years, respectively (5). Hidden infections continuing longer than 3 years have also been described (6). Development of Chlamydiae is highly dependent on nutrient supply and the metabolic status of the host cell (7). Although C. pecorum is frequently isolated from the digestive tract of ruminants with no clinical symptoms, it is a causative agent of fertility disorder, conjunctivitis, arthritis, mastitis, and pulmonary inflammation in sheep, goats and cattle (8). While C. psittaci can cause severe flu-like infections in humans, birds develop largely non-specific, and sometimes, fatal intestinal and respiratory symptoms (9). Moreover, the disease affects goats, and to a lesser degree, cattle, horses, pigs and deer, while little is known about the rate of these infections because of lack of epidemiological evidences (10). Although C. pecorum association in small ruminants abortion incidents was formerly described nearly 20 years ago in south of France (11), its role as an etiological agent of abortion is not well-known in humans. C. psittaci comprises a range of Chlamydia with diverse genetic, serological, and host-tropic properties. By DNA-DNA hybridization examination, 14% to 95% homology was reported among C. psittaci strains (11) and less than 70% among mammalian strains, and avian strains of C. psittaci. Moreover, C. abortus strains are widespread among ruminants and have been related to abortion in horses, rabbits, guinea pigs, mice, pigs and humans (12).

In addition to DNA-based techniques (polymerase chain reaction and DNA microarray) and RFLP, various diagnosis techniques, such as direct microscopic inspection, culture in embryonated chicken eggs, or in cell cultures, serological exams for protein detection (complement fixation test (CFT), enzyme-linked immunosorbent assay (ELISA) and immunohistochemistry and direct immunofluorescence) could be utilized to recognize Chlamydia and Chlamydia in biological samples (13). Conventional and real-time PCR methods have been implemented using PCR, which amplify conserved regions of the chlamydial outer membrane protein genes ompA, omp1, and omp2, the polymorphic membrane gene pmp, genes, or the intergenic space between the 16S and 23S rRNA genes (14, 15). Several studies on C. abortus in sheep and goats by serology (16) and C. psittaci in pigeons (17) by PCR have been documented in Khuzestan province. Considering suspected Chlamydia abortion (last 2-3 weeks of pregnancy) in ruminants (bovine, ovine and goat) in the 2 mentioned provinces and migration of animals to and from these 2 provinces, the aim of this research was the primary study on the presence of important Chlamydia spp. in aborted ruminants with doubtful signs of Chlamydia abortion.

MATERIALS AND METHODS

Preparation of clinical samples. A total of 117 aborted fetuses were collected from different herds located in southwest of Iran, where abortion had been observed during the lambing periods from 2014 to 2016. A total of 9 cattle and 100 sheep from Sasan and Lordegan in Cheharmahal and Bakhtiari province and 8 sheep from Bagh-e-Malek in Khuzestan province were selected. Sampling was targeted, meaning that only aborted fetuses at the last 2 to 3 weeks of gestation were selected and transferred to the laboratory on ice. Sampling was performed in sterile conditions from liver, spleen, and abomasal contents of aborted fetus. Laborious methods were performed to ensure that tissues were collected from the same anatomical location in each animal. Strict aseptic protocols, including the use of new sets of tools, were used to avoid cross-contamination. The samples were stored in sterile microtubes at -20°C till DNA extraction.

DNA extraction. Genomic DNA was extracted from the tissue samples using a SinaGen Kit (SinaGen, Iran), according to the manufacturer’s instructions. Tissue samples were finely chopped using sterile blades prior to extracting DNA. Genomic DNA extracted from each isolate was quantified using the Nano Drop spectrophotometer and stored in -20°C.
for the next genomic evaluation.

**PCR assay.** Precautions were taken to use sterile reagents and conditions; and contamination of reactions by PCR product was avoided by strict separation of working areas. The optimal PCR conditions for *C. abortus*, *C. psittaci* and *C. pecorum* individual amplification were initially determined separately using serial dilutions of respective DNA solution. The PCR reactions were performed in a final volume of 25 μL containing 12.5 microliter of master mix 2x (Ampliquen, Denmark) containing 1× PCR buffer, 200 μM of 4 deoxynucleoside triphosphate (dNTPs), 2 mM MgCl₂, and 0.5 U of *Taq* polymerase, then, 0.5 μM of each primer set and 2 microliter of extracted DNA were added to each reaction. PCR reactions were performed in an Eppendorf thermocycler (Eppendorf, Germany). Thermal conditions for amplification of *Chlamydiales* specific gene were initial denaturation for 5 minutes at 95°C, 39 one-minute cycles at 94°C, 45 seconds at an annealing temperature of 54°C, and elongation for 45 seconds at 72°C, with a final extension step at 72°C for 5 minutes. The PCR products were subjected to electrophoresis for 1 hour at 70V in 1.5% safe stain containing agarose gel, and the results were visualized and photographed under ultraviolet illumination. Detection of *C. pecorum* infection of samples was conducted by Nested-PCR. The name, sequence and the predicted amplified fragment of studied genes, as well as the annealing temperature are listed in Table 1. The standard strain DNA of *C. abortus* S26/3 and *C. pecorum* W73, obtained from Professor Borel (University of Zurich) as a gift, and *C. psittaci* 6BC, as obtained from Professor Sarryopoglu (University of Turkey) as gift, were used as positive controls for each round of PCR (18-20).

**RESULTS**

The samples were tested by conventional PCR to identify specific *16S rRNA* and *pmp* genes of *C. abortus* and *C. psittaci*, respectively. As expected, PCR amplification of DNA for *C. abortus* produced 222bp fragment and produced 300 bp fragments for *C. psittaci*. The annealing temperature of 54°C and 48°C were used for these PCR experiments, respectively (Figs. 1, 3).

Out of 117 doubtful chlamydial clinical samples taken from the infected animals (108 sheep and 9 cow), 66 (56.41 %) samples were detected by either one of the 3 pathogens. A total of 24 (36.36%) and 24 (36.36%) sheep samples were positive for *C. abortus* and *C. psittaci*, respectively. In this study, only 1 (1.5%) *C. pecorum* was identified from cattle by producing a 576-597 and 426-441 bp fragment using Nested-PCR. Annealing temperatures used in the first and second stages were 52°C and 50°C, respectively (Fig. 2).

The specificity of the PCR experiments using these primers were checked on genomic DNA samples from unrelated bacteria. None of the DNA samples from non-chlamydial bacteria created a measurable PCR bands in these experiments. No PCR product was produced using water instead of target DNA. The results are demonstrated in Table 2.

**DISCUSSION**

*Chlamydiaceae* family is considered as one of the main bacterium related to abortion in ruminants, such as sheep, goats, and cattle (21). Abortion is economically important in many herds of sheep and goats in Europe, North America, Africa, and Iran. The bacteria causes premature birth, reproductive disorders in ruminants, inflammation of the epididymis, pneumonia, arthritis, and conjunctivitis in the feces of healthy sheep and goats (22); also, it is a zoonotic risk for numerous pregnant women. It is reported that *C. abortus* can be spread in human placenta (9). This bacterial family is remarkably important. Thus, many studies have been conducted to identify and recognize these bacteria. For example, the prevalence of infection with this bacterium was reported to be 8.9% in a serological study by ELISA in sheep of Ahvaz, Iran (16). In house ELISA kit, based on rPOMP-90-3, 4 and 3+4 antigens were designed by Bakhtiari et al. to prevent available cross-reaction between *C. abortus* and *C. pecorum* in commercial kits (23). Moreover, in Mahzouniyeh et al. research (2014), *C. abortus* contamination in Shahr-e-Kord was reported to be 52% using Nested-PCR (24). In 2009, Pantchev et al. detected *C. psittaci* and *C. abortus* based on *ompA* gene from tissue samples using real-time PCR (25). Regular methods, such as bacterial culturing and staining, are slightly more sensitive in detecting *Chlamydia* bacterium in field samples. However, these methods are uncertain in most situations and are more difficult. The new development of different PCR assays has been described to detect *Chlamydia* bacterium in samples from the aborted fetuses (26). PCR provides a rapid diagnosis without the need for a culture

or identifying species and strains with more similarity. Also, PCR detection is not affected by the lack of viability of the microorganism and is more sensitive than culture in detecting non-feasible organisms and cellular DNA. Previous results have revealed that the PCR amplification of 16S rRNA genes is a good target for identifying Chlamydia spp. (15). Although there are different sets of primers that allow the identification of all species of the Chlamydiaceae family, PCR assays that amplify segments of the 16S rRNA genes present high sensitivity and specificity (27). Based on present results, C. abortus, C. psittaci and C. pecorum can be differentiated by PCR products obtained with species-specific primers to 16S rRNA, pmp and momp gene. The specificity of those primers allows the differentiation of C. abortus and C. pecorum using a conventional PCR. The fact that a considerable proportion of sheep samples (20 of 57 positive samples) were contaminated with 2 chlamydial agents is in line with previous study. The clinical features of abortion caused by C. abortus and C. psittaci are highly similar and such mixed infections have been proposed to be a common incidence in sheep and goat herds (28). Investigation of a large panel of diagnostic samples revealed an interesting epidemiological aspect, which was the occurrence of 2 chlamydial species in 1 sample. This was in agreement with previous findings (29) that reported the same species in pigs suffering from respiratory symptoms or fertility problems. Moreover, infections caused by C. suis, C. abortus, C. pecorum and C. psittaci were reported (30, 31). The existing data suggest that the sheep seem to be a host mainly susceptible to co-infections. In the present study, combinations of C. abortus and C. psittaci (35.08%) were regularly identified in sheep samples. A certain preference of C. abortus and C. psittaci to perform in concert with another chlamydial agent has already been reported (32). How does a bacterium that causes systemic disease in birds transform into an organism of mammalian abortion? The response will offer important visions into the mechanisms of chlamydial virulence and can finally be answered by genome sequence comparison. Until then, our capability to differentiate C. psittaci and C. abortus will remain to rely on ecological alterations, mAbs, and genetic data (16S or 23S rRNA signature sequences), and ompA, cysteine-rich proteins (27, 33, 34). In this study, PCR-amplification of momp gene, using specie-specific primers by nested-PCR, identified C. pecorum strain in cattle. Another study revealed that C. pecorum was more widespread in cattle than C. abortus and that the bacteria were frequently detected in vaginal swabs and fecal samples (35). Earlier data on C. pecorum involvement in abortion in Tunisia and Morocco indicated that C. pecorum may cause abortion in small ruminants in North African countries. Several studies have indicated that C. pecorum can also be a possible reason of abortion in ewes and goats (36). Clinically unclear intestinal infections produced by C. pecorum have already been reported in both abortion-affected and unaffected ruminant flocks (37). Also, the mixed infection of C. pecorum with C. abortus related to abortion in water buffalo in south of Italy (38) suggests that C. pecorum could also be associated with abortion in large ruminants. Consequently, differentiating the 2 species in abortion material is highly necessary. Nevertheless, it is still unknown whether C. pecorum-related abortion is a consequence of C. pecorum alone or is due to a development of its pathogenesis mediated by the coinfection with C. abortus; its pathogenicity may be related to a lack of nutrients or parasitic invasions, which frequently occur in these countries. It could also be considered that no pathogenic C. pecorum strains might be spread from the intestine through the blood circulation and reach the placenta, where they cause abortion due to some unidentified physiopathologic situations. The presence of 1 C. pecorum among 66 samples included in our study suggests that abortion by C. pecorum is rare in the region. Also, migration of the flocks toward Bagh-e-Malek and Shahr-e-Kord during winter and summer can cause co-contamination and simultaneous infection in these areas. Thus, as co-infections are not rare events, the combination of various specific diagnostic tests is crucial for epidemiological studies.
