Electric transport and scanning tunneling spectrum (STS) have been investigated on polycrystalline samples of the new superconductor Bi$_2$O$_4$S$_3$. A weak insulating behavior in the resistive curve has been induced in the normal state when the superconductivity is suppressed by applying a magnetic field. Interestingly, a kink appears on the temperature dependence of resistivity near 4 K at all high magnetic fields above 1 T when the bulk superconductivity is completely suppressed. This kink associated with the upper critical field as well as the wide range of excess conductance at low field and high temperature are explained as the possible evidence of strong superconducting fluctuation. From the tunneling spectra, a superconducting gap of about 3 meV is frequently observed yielding a ratio of $2\Delta/k_B T_c \approx 16.6$. This value is much larger than the one predicted by the BCS theory in the weak coupling regime ($2\Delta/k_B T_c \approx 3.53$), which suggests the strong coupling superconductivity in the present system. Furthermore, the gapped feature persists on the spectra until 14 K in the STS measurement, which suggests a prominent fluctuation region of superconductivity. Such superconducting fluctuation can survive at very high magnetic fields, which are far beyond the critical fields for bulk superconductivity as inferred both from electric transport and tunneling measurements.

Superconductivity is induced by quantum condensation of a large number of paired electrons. The pairing is supposed to be established between the two electrons with opposite momentum and spins by exchanging the phonons. According to the Bardeen-Cooper-Schrieffer (BCS) theory, a linear relationship between the electron pairing gap $\Delta$ and superconducting (SC) critical temperature $T_c$, i.e., $2\Delta/k_B T_c = 3.53$ exists in the weak coupling regime. In recent years, the original proposal about the pairing based on the electron-phonon coupling has been gradually replaced by the more exotic pairing mechanism, such as through exchanging the magnetic spin fluctuations, and $T_c$ can be increased to a higher level. The SC pairing mechanism of the cuprates$^2$ and the iron pnictides$^4$ have very weak correlation effect. It would be surprising to find out superconductivity with exotic feature in the p-orbital based compounds.

Recently, Mizuguchi et al$^{22}$ discovered superconductivity with $T_{c\text{onset}} = 8.6$ K (determined from the point where resistivity deviates from the linear extrapolation of normal-state value) and $T_{c\text{zero}} = 4.5$ K in the so-called Bi$_2$S$_3$ based compound Bi$_4$O$_4$S$_3$. This compound has a layered structure with the space group of I4/mmm or I-42m. Shortly the same group reported superconductivity with $T_{c\text{onset}} = 10.6$ K in another system LaO$_{1-x}$F$_x$Bi$_2$ by doping electrons into the material through substituting oxygen with fluorine$^{23}$. By replacing the La with Nd or Ce, other new Bi$_2$S$_3$ based materials were reported$^{24,25}$. Quickly followed is the theoretical work based on the first principles band structure calculations$^{26}$, which predicts...
that the dominating bands for the electron conduction as well as for the superconductivity are derived from the Bi $6p_x$ and $6p_y$ orbits. In this paper, we present a set of data for an intensive study on the transport and scanning tunnelling spectroscopy (STS) measurements of the new superconductor $\text{Bi}_4\text{O}_3\text{S}_3$. Our results clearly illustrate the strong coupling superconductivity and prominent superconducting fluctuation in this interesting superconductor.

I. EXPERIMENTS

The polycrystalline samples were synthesized by using a two-step solid state reaction method. Firstly, the starting materials bismuth powder (purity 99.5%, Alfa Aesar) and sulfur powder (purity 99.99%, Alfa Aesar) were mixed in a ratio of 2:3, ground and pressed into a pellet shape. Then it was sealed in an evacuated quartz tube and followed by annealing at 500°C for 10 hours. The resultant pellet was smashed and ground together with the $\text{Bi}_2\text{O}_3$ powder (purity 99.5%, Alfa Aesar) and sulfur powder, in stoichiometry as the formula $\text{Bi}_4\text{O}_3\text{S}_3$. Again it was pressed into a pellet and sealed in an evacuated quartz tube and burned at 510°C for 10 hours. Then it was cooled down slowly to room temperature. The second step was repeated in achieving good homogeneity. The resultant sample looks black and very hard. We cut the sample and obtained a specimen with a rectangular shape for the resistive measurements. The resistivity was measured with Quantum Design instrument PPMS-16T. The magnetization was detected by the Quantum Design instrument SQUID-VSM with a resolution of about 5 x $10^{-8}$ emu. The sample was shaped as a bar with a typical size of $2 \text{mm} \times 2 \text{mm} \times 0.5 \text{mm}$ for the STS measurements. Since the sample is very hard, which allows us to polish the sample surface and obtain a shiny and mirror-like surface. The top surface was polished by sandpapers with different grit sizes (smallest of ISO P10000). The tunnelling spectra were measured with an ultra-high vacuum, low temperature and high magnetic field scanning probe microscope USM-1300 (Unisoku Co., Ltd.). In STS measurements, Pt/Ir tips were used. The set points of the bias voltage and tunnelling current are 40 mV and 100 pA respectively to fix the tip height in topographic mode. Then the differential conductivity was recorded while the bias voltage was swept with the tip held at a fixed vertical distance with $z$ -piezo-feedback off for the STS measurements. There is no atomically resolved topography measured on the sample since it is a polycrystalline one. The roughness of the surface for STS measurements is about 2 nm, while on some flat surface of a grain the roughness is about 0.5 nm locally. The STS spectra are repeatable at different positions in one grain. In reducing noise of the differential conductance spectra, a lock-in technique with an ac modulation of 0.1 mV at 987.5 Hz was typically used.

II. RESULTS

The crystallinity of the sample was checked by x-ray diffraction (XRD) with the Brook Advanced D8 diffractometer with Cu Kα radiation. The analysis of XRD data was done by the softwares Powder-X and Topas. The XRD pattern looks very similar to that reported by Mizuguchi et al.\textsuperscript{22}. The result of Rietveld fitting was done with the Topas program in Fig. 1, yielding a 80% volume of $\text{Bi}_4\text{O}_3\text{S}_3$ with 20% of impurities which are mainly $\text{Bi}_2\text{S}_3$ (15%) and Bi (5%).

In Fig. 2(a) we present the temperature dependence of resistivity measured at three magnetic fields: $\mu_0H =0$, 6 and 14 T. In addition to the moderate magnetoresistance, one can see that a weak insulating behavior is induced by the magnetic field. This weak semiconducting behavior is of course anti-intuitive for a normal state with Fermi liquid characteristic. A simple explanation would be that the insulating feature is given by an adjacent competing order here, once the superconductivity is suppressed, the latter is getting promoted. However, we should mention that the insulating behavior starts actually at 25 K (at 6 and 14 T) which is far beyond the SC transition temperature here. Someone may argue the minimum in the resistivity is caused by some impurities of Bi$_2$S$_3$, which shows a minima around 25 K, but this may be excluded because we do not see this phenomenon in zero magnetic field. Another possibility is that the conduction band has a very shallow band edge, as illustrated by the band structure calculations.\textsuperscript{26} When a magnetic field is applied, the density of states (DOS) of the spin-up and spin-down electrons will become asym-
metic given by the Zeeman effect. Therefore we have some polarized electrons which induce the weak insulating behavior. Clearly this insulating behavior needs to be further checked, better with single crystals in the future, and to be explained satisfactorily. In Fig. 2(b) we present the magnetization data measured in the zero-field-cooled (ZFC) and the field-cooled mode (FC). The SC magnetic transition starts at about 3.6 K. Superconducting transition temperature in this paper is a little lower than that in previous report by Mizuguchi et al., probably due to mutual doping between the O and S elements. From the resistive curve in the transition region as shown in Fig. 3(a), the critical temperature taken from 5% of the normal state resistivity (\(T_{\text{c}0}\) or \(T_{\text{on}}\)) is 3.7 K. The onset transition temperature \(T_{\text{c}0}\) determined from the crossing point of the normal state background (guided by a blue dash-dot line) is 4.2 K. The resistance difference between the resistive curve and the normal state background extends to a very high temperature shown in the inset, which suggests that the SC fluctuation may be strong in this material. (b) An enlarged view for the temperature dependence of resistivity at magnetic fields of (from bottom to top) 0, 0.1 to 0.6 T with increments of 0.1 T; 0.8, 1, 1.5, 2 to 7 with increments of 1 T; and 9, 12, 14 T. It is found that the bulk superconductivity can be quickly suppressed by the magnetic field, while the onset transition temperature changes slightly, indicating a strong fluctuation effect. (c) Temperature dependence of the resistivity as shown in (b) normalized at 10 K. A kink can be clearly seen at about 4 K when the magnetic field is high and the bulk superconductivity is suppressed completely. The red arrowed line traces out the evolution from the SC onset transition in the low field region to a kink at high magnetic fields.
conducting gap is found by STS measurements as a peak feature at a higher energy outside of the superconductors, sometimes a bosonic mode which exhibits the ratio $2\Delta_2/\Delta_1$ in the low field and high temperature region. Because it is really difficult to define the temperature below which $\rho_s$ first deviates from its high temperature behavior, we use these kink positions to define the upper critical fields above 1 T. Surprisingly, this kink stays at about 4 K even with a magnetic field of 14 T. We interpret this kink as the temperature below which the residual Cooper pairs exist in the system even the bulk superconductivity is completely suppressed. Following the tendency of this kink, a very high critical field can be expected in the zero temperature limit, which certainly exceeds the Pauli limit given by $\mu_0H_{c2}$ in the low field and high temperature region.

To make further analysis on the superconducting property, we measured STS spectra on this sample. Several typical STS curves measured at 1.6 K below the bulk SC transition are shown in Fig. 3(a). Most of the spectra are symmetric with very clear suppression of DOS within a certain energy scale, and clear coherence peaks can be found on some spectra. However the coherence peaks on most of the curves are somewhat broad and the zero-bias conductance values are remarkably large, which may be due to the contamination of the surface on this polycrystalline sample. The gap values determined from the coherence peaks or the kink position to the superconducting feature marked by the depression of the density of states at the Fermi level are shown in Fig. 4(b). One can see that the mean gap value $\Delta = 3$ meV. Such a large gap value suggests the unconventional superconductivity in Bi$_2$O$_3$S$_3$ with $T^*_{c}(\text{onset}) = 4.2$ K. The largest SC gap can reach a value of about 10 meV superconductors. This suggests the very strong coupling superconductivity in the superconductor. Since the scattering is really strong in the polycrystalline sample, it is very difficult to judge the pairing symmetry from the fitting to the spectra. As shown in Fig. 3(b), the gap size follows the Gaussian distribution with the mean gap value $\Delta = 3$ meV. Such a large gap value suggests the unconventional superconductivity in Bi$_2$O$_3$S$_3$ with $T^*_{c}(\text{onset}) = 4.2$ K. The largest SC gap can reach a value of about 10 meV superconductors. This suggests the very strong coupling superconductivity in the superconductor. Since the scattering is really strong in the polycrystalline sample, it is very difficult to judge the pairing symmetry from the fitting to the spectra. As shown in Fig. 3(b), the gap size follows the Gaussian distribution with the mean gap value $\Delta = 3$ meV. Such a large gap value suggests the unconventional superconductivity in Bi$_2$O$_3$S$_3$ with $T^*_{c}(\text{onset}) = 4.2$ K. The largest SC gap can reach a value of about 10 meV superconductors. This suggests the very strong coupling superconductivity in the superconductor. Since the scattering is really strong in the polycrystalline sample, it is very difficult to judge the pairing symmetry from the fitting to the spectra. As shown in Fig. 3(b), the gap size follows the Gaussian distribution with the mean gap value $\Delta = 3$ meV. Such a large gap value suggests the unconventional superconductivity in Bi$_2$O$_3$S$_3$ with $T^*_{c}(\text{onset}) = 4.2$ K. The largest SC gap can reach a value of about 10 meV superconductors.
FIG. 5: (color online) (a) The evolution of the tunnelling spectra taken at temperatures from 1.6 K to 20 K. The spectra are displaced vertically for clarity. (b) The STS normalized by the one measured in normal state (at 20 K). One can see that the gapped feature vanishes at about 14 K which is much higher than the critical temperature for bulk superconductivity ($T_c(99\%\rho_n) \sim 6$ K), as shown by the blue curve.

FIG. 6: (color online) (a) The evolution of the tunnelling spectra at different magnetic fields up to 10 T at 1.6 K. The spectra are displaced vertically for clarity. The spectrum taken at 20 K and 0 T is also shown for comparison. (b) The STS curves normalized by the one measured in normal state (at 20 K and 0 T). One can see the suppression of DOS remains at fields above the bulk upper critical field $H_c(99\%\rho_n) \sim 5$ T.

The pseudogap effect can also be observed from the kink in resistive curve in cuprates. Because we cannot find any trace of pseudogap from the transport measurements, this effect at high temperature is supposed to be the SC fluctuation instead of the pseudogap. In addition, the estimation is consistent with excess conductivity at the temperature above bulk $T_c$. If using $T_f = 14$ K as the pairing temperature, we get the ratio $2\Delta/k_B T_f \sim 5.0$ which is still a large value but comparable with the value calculated from the SC gap and the pseudogap temperature in cuprates. It should be noted that some SC gap values could extend to very high, i.e., larger than 7 meV, which gives a much larger value of $2\Delta/k_B T_f$. The detailed reason for this large energy gap remains unresolved.

Figure 3(a) shows the STS spectra taken at different magnetic fields at the same temperature 1.6 K. The bulk upper critical field $\mu_0 H_{c2}$ judged from the 99% of the normal state resistance at 1.6 K is about 5 T. The suppression to the DOS on the spectra are apparently without any variation when crossing this bulk transition temperature, and it is more clear for the normalized spectra by dividing out the background spectrum taken at 20 K and 0 T as shown in Fig. 3(b). As described above, the gapped feature on the spectra existing above $T_c(99\%\rho_n)$ is consistent with the picture of fluctuating superconductivity. Since the spectra at high magnetic fields are similar to those taken at zero field but at high temperatures, this suppression of DOS near Fermi energy observed above bulk $H_c(99\%\rho_n)$ can also be attributed to the SC fluctuation and preformed Cooper pairs.

III. DISCUSSION

Next we present a phase diagram based on the transport and STS measurements in Fig. 7 and give discussions on the possible mechanism of superconductivity. The SC transition point of critical field $H_c(99\%\rho_n)$ is shown by the red filled circles. The bulk superconductivity is established in a very small area covered by the irreversibility line $T_{irr}$ (blue up-triangles). The large area between them indicates a strong SC phase fluctuation. This is actually consistent with the theoretical expectation because the electronic system has one dimensional feature ($\rho_x$ and $\rho_y$). The bulk superconductivity is established between the one dimensional fluctuating superconducting chains. The curve marked with $H_c^{\text{onset}}$ gives the upper critical
field determined using the usual crossing point of the normal state background and the extrapolated line of the steep resistive transition part. The most puzzling behavior is induced in the normal state when a high magnetic field is applied. This can be induced either by an adjacent competing order, or the very shallow $p_x$ and $p_y$ bands and small Fermi energy. A kink appears on the temperature dependence of resistivity at all high magnetic fields when the bulk superconductivity is completely suppressed. This kink can be regarded as the presence of local pairing, or the upper critical field $H_{c2}(T)$. The SC fluctuation region from the STS measurement extends to about 14 K although the bulk superconducting transition temperature is only about 3.7 K. The gapped feature near the Fermi energy can also extend to a high magnetic field ($\sim 5$ T), which is consistent with the resistive measurements, again indicating a strong superconducting fluctuation. From the tunnelling spectra, a mean superconducting gap of 3 meV is widely observed, which leads to a very high ratio of $2\Delta/k_BT_c \approx 16.6$, suggesting strong coupling superconductivity.

We appreciate the useful discussions with WANG Fa, FU Liang, WANG QiangHua and LI JianXin. **IV. CONCLUSIONS**

In summary, we perform the resistive and scanning tunnelling spectroscopy measurements on the new BiS$_2$ based superconductor Bi$_4$O$_3$S$_3$. A weak insulating behavior is induced in the normal state when a high magnetic field is applied. This can be induced either by an adjacent competing order, or the very shallow $p_x$ and $p_y$ band and small Fermi energy. A kink appears on the temperature dependence of resistivity at all high magnetic fields when the bulk superconductivity is completely suppressed. This kink can be regarded as the presence of local pairing, or the upper critical field $H_{c2}(T)$. The SC fluctuation region from the STS measurement extends to about 14 K although the bulk superconducting transition temperature is only about 3.7 K. The gapped feature near the Fermi energy can also extend to a high magnetic field ($\sim 5$ T), which is consistent with the resistive measurements, again indicating a strong superconducting fluctuation. From the tunnelling spectra, a mean superconducting gap of 3 meV is widely observed, which leads to a very high ratio of $2\Delta/k_BT_c \approx 16.6$, suggesting strong coupling superconductivity.
