Quantum transport phenomena play a central role in many areas in physics, such as coherently controlled photocurrent in semiconductors [1] or atoms in optical lattices [2]. Non linearity can lead to interesting effects even for really simple models, with numerous applications, such as dynamics of Josephson junctions [3] and electronic transport through superlattices [4], to cite a few. Symmetries in the system are of fundamental importance, as their presence or absence can enhance or destroy (quantum) interferences, and can therefore strongly affect transport properties. In particular, in systems with broken parity symmetry, one can observe directed transport [5]. The breaking of time reversal symmetry can also lead to directed transport [6], an example being the ratchet effect, that is, the existence of directed transport without a bias field in periodic systems.

The study of the ratchet effect was stimulated by the research on Brownian molecular motors e.g. in biological systems, and was investigated in different simple noisy models [7]. In its original formulation, this effect is of stochastic nature, due to an external (for instance thermal) noise. A possible variant are the so-called Hamiltonian chaotic ratchets [8–10], where the extrinsic noise is replaced by deterministic chaos, possibly in presence of dissipation [6, 11–15]. These ratchets require mixed phase spaces displaying regular regions embedded in a chaotic sea [9]. However, it can be shown that in a Hamiltonian chaotic ratchet the current averaged on the whole phase-space is always zero for unbiased potentials. The accelerated islands in phase-space contribute to directed transport but this effect is globally compensated by the motion of the remaining part of the phase space, the chaotic sea [8, 9].

The kicked rotor is a paradigm of classical chaotic dynamics, displaying, according to parameters, a regular, mixed or ergodic phase space. It is also known to display accelerator modes, with a distinct ballistic behavior. In its quantum version the Quantum Kicked Rotor (QKR) is a benchmark model for quantum simulations, intensively in the context of quantum chaos [16]. Moreover, it has been shown to display the striking phenomenon of dynamical localization [17, 18]: at long times, the diffusive classical dynamics is inhibited by quantum effects, which have been shown mathematically to be equivalent to the Anderson localization in momentum space [19]. The first realization of the QKR using cold atoms [20] has triggered numerous experiments in the field of quantum chaos [21–24]. In particular, adding a quasi-periodic modulation of the kick amplitude allows one to maps the system onto multidimensional Anderson models [25, 26]. This made it possible to study 2D Anderson localization [27], and to fully characterize the 3D metal-insulator Anderson transition [28–32].

In this work we use the cold-atom realization of the Kicked Rotor to, i) demonstrate that directed motion can be generated if the system’s parity invariance is broken, ii) characterize the classical anomalous diffusion of the chaotic sea, and iii) show that the subtle quantum interferences at the origin of dynamical localization have the striking effect of counteracting this directed classical transport. At long times, the transport asymmetry associated with the ratchet dynamics disappears and the system undergoes dynamical localization, associated with a symmetrical wave function with a characteristic universal shape.

The kicked rotor is known to support so-called “accelerator” modes [33]. However, the standard KR Hamiltonian displaying both time-reversal and parity symmetry, if some initial condition \((x_0, p_0)\) leads to classical motion in one direction, say \(+x\), parity symmetry implies that “conjugated” initial condition \((-x_0, -p_0)\) will lead to an equivalent motion in the \(-x\) direction. In this work we use a modified Hamiltonian [34], that allows us to easily...
that can be changed in the experiment (see below). For sequence One can show that the following periodic phase-shift relation

\[
\hat{H}(t) = \frac{\hat{p}^2}{2} + K \sum_n \cos(\hat{x} + a_n) \delta(t - n),
\]

where we use dimensionless units such that position and momentum operators obey the canonical commutation relation \([\hat{x}, \hat{p}] = i\hbar\), where \(\hbar\) is an effective Planck constant that can be changed in the experiment (see below). For \(a_n = 0, \forall n\), we retrieve the usual QKR Hamiltonian \([17]\). One can show that the following periodic phase-shift sequence \(a_n = \varphi_n [\text{mod. 3}]\), with \(\{\varphi_1, \varphi_2, \varphi_3\} = \{0, 2\pi/3, 0\}\) produces a breaking of the parity symmetry \([35]\). In the following, we will focus on relatively small values of \(k\), in the range \(0.8 – 1.3\), allowing us to study both the (semi-) classical dynamics and dynamical localization. A similar Hamiltonian displaying an interplay between a quantum resonance, observed for \(k = 2\pi\), and accelerator modes has been studied experimentally \([24, 36, 37]\). In our case, in contrast, the ratchet effect is purely classical, and is therefore independent of the value of \(k\).

Our experiment is performed with a cold \((T \approx 2.4\mu K)\) cloud of cesium atoms kicked by a periodically-pulsed, far-detuned standing wave \((\Delta = -13\text{ GHz} \text{ with respect to the D}2\text{ line at } ~ 852\text{ nm})\). The beam waist is \(\sim 800\mu m\) for a \(330\text{ mW}\) one-beam power. The standing wave is built by the overlap of two independent, arbitrarily-phase-modulated, laser beams. This feature allows us to dynamically shift the potential position, and thus to synthesize Hamiltonian (1). Time is measured in units of the standing wave pulse period \(T_1\), space in units of \((2k_L)^{-1}\) with \(k_L = 2\pi/\lambda_L\) the laser wave vector, and momentum in units of \(M/2k_L T_1\) so that \(k = 4\hbar^2 k_L^2 T_1/M\) (with \(M\) the atomic mass). At the maximum velocity reached by the atoms \(v_{\text{max}} = 0.55\text{ m/s}\), the atoms move during the pulse duration \(\tau = 200\text{ns}\) of a distance \(v_{\text{max}}\tau = 110\text{ nm}\), for \(k = 0.8\). Experimentally, the population of the peak at the left of the plot is 14.5%. The quantum simulation is shown as the black dashed line. Right panel: Superposition of three successive classical phase space structures generated by the Hamiltonian (1) each corresponding to 1/3 of the full period of the system. There is thus only one island, whose position is displayed at each 1/3 of the period. Because the classical standard map is periodic in both \(x\) and \(p\), it is possible to fold the phase space in the \([0, 2\pi]\times[0, 2\pi]\) square. In the unfolded phase space, the island is moving continuously to the left.

break parity symmetry

\[
\hat{H}(t) = \frac{\hat{p}^2}{2} + K \sum_n \cos(\hat{x} + a_n) \delta(t - n),
\]

where we use dimensionless units such that position and momentum operators obey the canonical commutation relation \([\hat{x}, \hat{p}] = i\hbar\), where \(\hbar\) is an effective Planck constant that can be changed in the experiment (see below). For \(a_n = 0, \forall n\), we retrieve the usual QKR Hamiltonian \([17]\). One can show that the following periodic phase-shift sequence \(a_n = \varphi_n [\text{mod. 3}]\), with \(\{\varphi_1, \varphi_2, \varphi_3\} = \{0, 2\pi/3, 0\}\) produces a breaking of the parity symmetry \([35]\). In the following, we will focus on relatively small values of \(k\), in the range \(0.8 – 1.3\), allowing us to study both the (semi-) classical dynamics and dynamical localization. A similar Hamiltonian displaying an interplay between a quantum resonance, observed for \(k = 2\pi\), and accelerator modes has been studied experimentally \([24, 36, 37]\). In our case, in contrast, the ratchet effect is purely classical, and is therefore independent of the value of \(k\).

Our experiment is performed with a cold \((T \approx 2.4\mu K)\) cloud of cesium atoms kicked by a periodically-pulsed, far-detuned standing wave \((\Delta = -13\text{ GHz} \text{ with respect to the D}2\text{ line at } ~ 852\text{ nm})\). The beam waist is \(\sim 800\mu m\) for a \(330\text{ mW}\) one-beam power. The standing wave is built by the overlap of two independent, arbitrarily-phase-modulated, laser beams. This feature allows us to dynamically shift the potential position, and thus to synthesize Hamiltonian (1). Time is measured in units of the standing wave pulse period \(T_1\), space in units of \((2k_L)^{-1}\) with \(k_L = 2\pi/\lambda_L\) the laser wave vector, and momentum in units of \(M/2k_L T_1\) so that \(k = 4\hbar^2 k_L^2 T_1/M\) (with \(M\) the atomic mass). At the maximum velocity reached by the atoms \(v_{\text{max}} = 0.55\text{ m/s}\), the atoms move during the pulse duration \(\tau = 200\text{ns}\) of a distance \(v_{\text{max}}\tau = 110\text{ nm}\), small compared to the characteristic scale of the potential \(\lambda_L/2 = 426\text{ nm}\); for most atoms one can thus consider our kicks as Dirac delta functions. For \(K \propto \sqrt{\Delta} = 3.1\) the lattice depth is about \(200\text{ }E_r\) where \(E_r = \hbar^2 k_L^2/2M\) is the recoil energy. For these experimental parameters the decoherence time is approximately 300 kicks. The main source of decoherence are the phase fluctuations of the laser beams forming the standing wave.

The quantum dynamics of the gas can also be simulated using a Monte-Carlo method: we choose a random initial momentum \(p_0\) according to the distribution

\[
|\psi_0(p)|^2 = \frac{1}{(2\pi\sigma^2)^1/2} e^{-\frac{p^2}{2\sigma^2}},
\]

which mimics the initial distribution of the atoms, where \(\sigma = 1.65k\) is the width of the thermal distribution of the atomic cloud (corresponding to \(T = 2.4\mu K\) in the experiment). The plane wave \(p_0\) is a Bloch wave for the spatially periodic Hamiltonian (1), with Bloch vector \(\beta = \text{frac}(p_0/k)\), which makes it possible to propagate it using the discrete basis set composed of eigenstates of the momentum operator \((m+\beta)k\) with \(m\) an integer. The final momentum density is obtained by averaging the individual momentum densities over \(10^4\) random initial momenta. Because \(\sigma \gtrsim k\) the resulting \(\beta\) distribution is almost uniform.

We first analyze the short-time dynamics for a relatively small \(k = 0.8\) (corresponding to \(T_1 = 7.67\mu s\)). The left panel of Fig. 1 compares the experimentally measured momentum distribution \(\Pi(p, n)\) after \(n = 15\) kicks to both the classical and the quantum simulation of the dynamics. The classical result matches very well with the experiments, and demonstrates that the short-time dynamics is effectively classical. The most striking feature of the momentum distribution is the sharp peak at
ballistic peak going to the left (at a velocity of $p = -31.2 \simeq 15 \times (-2\pi/3)$, which will be shown to transport ballistically (in momentum) toward the left (negative $p$), $P_{\text{peak}}(n) = -2\pi n/3$. The right panel Fig. 1 shows the classical phase portrait obtained by evolving with the classical version of Hamiltonian (1) $2 \times 10^3$ initial conditions $(x_0, p_0)$, with $x_0$ uniformly sampled and $p_0$ sampled according to Eq. (2). This provides a clear interpretation of the accelerator mode mechanism, corresponding to the transport of a regular island across the classical phase-space. The island’s center obeys the recursion condition $(x_{n+3}, p_{n+3}) = (x_n, p_n - 2\pi)$; as the maximum momentum transferred by one kick is $K$, changing $|p|$ by $2\pi$ each 3 kicks requires $K \geq 2\pi/3$ for the accelerator mode to exist [38]. The value $K \simeq 3.1$ we use here allows for the largest possible island.

Figure 2 (left) shows a false-color plot of the experimentally measured momentum distribution $\Pi(p, n)$ as a function of both $p$ and $n$. One clearly observes the ballistic peak going to the left (at a velocity of $-2\pi/3$ per kick), and a anomalous-diffusive front propagating to the right. Indeed, has been shown that the presence of accelerator modes is associated with an anomalous diffusion $\langle p_n^2 \rangle \propto n^\zeta$, with a non-universal exponent $\zeta \in [1, 2]$ [10, 39, 40]. The momentum distribution is thus strongly asymmetric due to these very different behaviors at the right and the left wings. Furthermore, the population of the peak is seen to decrease with time.

In contrast to the standard QKR, for which accelerator modes always appear in counter-propagating pairs, the fact that our setup breaks the parity symmetry allows for directed motion. Since unbiased classical map, such as the one studied here, cannot display a net current when averaged over phase-space [8, 9], the dynamics of the chaotic sea must compensate the motion of the ballistic peak [41].

Thanks to the very good resolution of our experiment, we were able to make precise measurements of the kinetic energy of the system. We can extract the kinetic energy contribution of positive momenta $(p > 0)$ $\langle p_n^2 \rangle_R = \int_{p > 0} p^2 \Pi(p, n) dp$, corresponding to the anomalously-diffusive chaotic sea, and could thus determine by a fit the anomalous diffusion exponent $\zeta \simeq 1.35 \pm 0.05$, which is in good agreement with both our classical and quantum simulations, see Fig. 2 (right). This is, to the best of our knowledge, the first experimental evidence of the anomalous diffusion behavior of the chaotic sea. The anomalous diffusion is usually interpreted in terms of chaotic trajectories which spend a long time close to the accelerated islands, thus performing Lévy flights in the same direction as the island [42]. Here, however, while the accelerated island propagates to the left, the anomalous diffusion goes in the opposite direction. Thus, the precise mechanism responsible for this anomalous diffusion remains an interesting open question.

For generic values of $K$ and $k$, the long-time dynamics of the QKR is governed by subtle quantum interferences which lead to dynamical localization: asymptotically, momentum distributions are exponentially localized. As the Hamiltonian of our system is time-periodic (period 3) and one-dimensional, one generically expects the Floquet states to be exponentially (Anderson) localized and the temporal dynamics of an initially localized wavepacket to display the standard dynamical localization at long times, possibly with a very large localization length [43]. In order to observe the localization experimentally before decoherence effects become important, we have slightly increased the value of $k \simeq 1.3$ (correspond-
In conclusion, we have shown that the careful crafting of our experimental setup allows us to break the parity symmetry and observe a classical Hamiltonian ratchet effect accompanied by an anomalous diffusion in the short-time dynamics. At longer times, dynamical localization leads to a striking re-symmetrization of the momentum distribution. It would be interesting to better characterize the mechanism leading to an anomalous diffusion in the direction opposite to the acceleration mode. Also, the quantum leaking from the classical island into the chaotic sea is important in the context of chaos assisted tunneling [48]. This illustrates the exciting perspectives accessible when the deep classical regime ($k \ll 1$) is attained experimentally. These challenging and interesting questions are left for future work.

We have checked the vanishing of current explicitly in numerical simulations of the classical and quantum dynamics, and it is well verified in the experiment. The finite duration of the kicks can affect the experimental momentum distribution at large momenta, but does not change qualitatively our results. This has also been checked extensively by comparison to numerical simulations.
