1. THE ATLAS ELECTROMAGNETIC CALORIMETER

The ATLAS electromagnetic (EM) calorimeter is a lead/liquid argon sampling calorimeter with accordion shaped electrodes and absorbers interleaved. The calorimeter is divided in two half barrel cylinders covering the pseudorapidity range $|\eta| \leq 1.475$, housed in a single cryostat and two endcap detector (covering $1.375 \leq |\eta| \leq 3.2$) housed in two separate endcap cryostats. Its accordion structure provides complete $\phi$ symmetry without azimuthal cracks. The total thickness of the calorimeter is greater than 22 radiation lengths ($X_0$) in the barrel and 24$X_0$ in the endcaps. The EM calorimeter is highly segmented with a 3-fold granularity in depth and $\eta \times \phi$ granularity of 0.0003 $\times$ 0.1, 0.025 $\times$ 0.025, and 0.05 $\times$ 0.025, respectively in the front, middle and back compartment. A pre-sampler with a fine granularity in $\eta$ ($\Delta \eta = 0.025$) is located before the cryostat and the coil, enabling to correct for the corresponding dead material effects. More details on the ATLAS detector can be found in [2].

2. ELECTROMAGNETIC CALIBRATION

The energy measurement in the calorimeter cells is the starting point of the reconstruction of electrons and photons. The construction of cell clusters is based on two algorithms, fixed-size window clusters for photons and topological clusters for electrons. The fixed-size algorithm starts by choosing a seed cell in the middle layer of EM calorimeter and then varies the position of a window to maximize the total energy contained in it. For the topological cluster, cells are chosen as seeds if their energy is above a given threshold. Since the material in front and the segmentation of the calorimeter affect the measured energy and position of EM clusters, position and energy corrections are applied at the cluster level. Due to the finite granularity of the detector, the difference between the true and the computed shower barycenter, as a function of the $\eta$ position inside the cell, has a typical S-shape. The cluster position in $\phi$ is determined from the energy barycenter in the second sampling. The measurement of $\phi$ is biased by an offset due to the accordion shape and depends on the distance to the folds of the accordion. The energy of a cluster is obtained by $E_{rec} = \lambda b + \omega_0 E_0 + E_1 + E_2 + \omega_3 E_3$, where $E_0, E_1, E_2$ and $E_3$ are the energies in the pre-sampler and the three layers of calorimeter. The offset term $b$ corrects for upstream energy loss before pre-sampler. The parameters $\lambda, b, \omega_0,$ and $\omega_3$, called longitudinal weights, are calculated by a $\chi^2$ minimization of $(E_{true} - E_{rec})^2/\sigma(E_{true})^2$ using Monte Carlo single particle samples.

Figure [1] shows the resolution as a function of the particle energy for electrons and photons at $|\eta| = 0.3$ and $|\eta| = 1.65$. The fits shown allow the extraction of a sampling term of the order of $10\%/\sqrt{E[GeV]}$ and a small constant term $[3].$ This result is confirmed by the analysis of real test beam data [4].
Figure 1: Energy resolution for electrons and photons at $|\eta| = 0.3$ and $|\eta| = 1.65$, as function of incoming energy. This is obtained by using simulated single electron and photon samples.

Figure 2: (a) The invariant mass of four electrons ($m_{eeee}$) from Higgs boson decay samples with $m_H = 130$ GeV (using calorimetric information only, with no Z boson mass constraint). (b) The invariant mass of two photons ($m_{\gamma\gamma}$) from Higgs boson decay with $m_H = 120$ GeV. The shaded plot corresponds to at least one photon converting at $r < 80$ cm.

Figure 2 (a) shows the reconstructed distribution of the invariant mass of the electrons after calibration, in the $H \rightarrow eee$ decay, with $m_H = 130$ GeV. The central value is correct at the 0.7% level and with a Gaussian resolution of 1.5%. Figure 2 (b) shows the reconstructed photon pair invariant mass for $H \rightarrow \gamma\gamma$ decays with $m_H = 120$ GeV. The central value of the reconstructed invariant mass is correct at 0.2% level and with a Gaussian resolution of 1.2%.

Using the clean and large-statistics sample of $Z \rightarrow ee$, it is possible to evaluate the overall EM energy scale of the calorimeter from the data, and to determine precisely the inter calibration between different regions of the calorimeter. Monte Carlo-based evaluations, using 87,000 reconstructed $Z \rightarrow ee$ events, shows that the long-range constant term can be kept below 0.5% [3]. This gives a global constant term below the design value of 0.7%.

3. ELECTRON AND PHOTON RECONSTRUCTION

The sliding window algorithm is used to find and reconstruct EM clusters. This forms rectangular seed clusters with a fixed size, $0.125 \times 0.125 (\eta \times \phi)$, positioned to maximize the amount of energy within the cluster. The combined reconstruction and classification checks whether a track can be matched to the seed cluster. If yes and the track does not correspond to a conversion, it is classified as an electron, else as a photon. The cluster is calibrated according to the particle hypothesis (electron/photon) with an optimized cluster size.

Due to the structure of the ATLAS tracker, photons which convert within 300 mm of the beam axis are associated with a track seeded in the silicon volume, while photons which convert further away from the beam pipe are found using tracks seeded in the Transition Radiation Tracker (TRT) [5] with or without associated hits in the silicon detector volume [5]. To reconstruct converted photon vertices, a dedicated vertex finder algorithm is used. Combining
In the Log-Likelihood Ratio (LLR) method, the distribution of each of the shower variables is normalized to unity to obtain a probability density function (PDF). Once the PDF’s are established, the LLR value is computed as 

$$\text{LLR} = \sum_{i=1}^{n} \ln(L_{s_i}/L_{b_i}),$$

where $L_{s_i}$ and $L_{b_i}$ are PDF’s of the $i^{th}$ shower shape variable for the real electrons/photons and the jets, respectively. Figure 4 (a) shows the distribution of LLR for photons and jets. The LLR cut can be tuned in bins of $\eta$ and $p_T$ to obtain an optimal separation between photons and jets.

The H-matrix method exploits the correlations among transverse and longitudinal shower shape variables to identify electrons and photons. The resemblance of a candidate to an electron or a photon shower is quantified by 

$$\chi^2 = \sum_{i,j=1}^{dim=10} (y_i - \bar{y}_i)H_{ij}(y_j - \bar{y}_j),$$

where $H = M^{-1}$ is the inverse of the covariance matrix $M$ of the shower shape variables, and the indices $i$ and $j$ run from 1 to the total number of variables, namely 10. The shape of the distributions of the selected shower shape variables depend on the $\eta$ and energy of the incoming photon or electron.
These effects are taken into account in the construction of the H-matrix using single photon or electron samples of different energies, to parameterize each of the covariance terms in the matrix $M$ as a function of photon or electron energy. The separation power of the H-matrix between real photons and jets is illustrated in Figure 4 (b), where the $\chi^2$ distribution of the H-matrix for the jet samples is compared to that obtained for photons from the $H \rightarrow \gamma\gamma$ decay.
